Abstract: Polyphase continuous waveform radar systems often use polyphase P4 modulation because of the periodic autocorrelation zero sidelobes and good Doppler tolerance. The P4’s unambiguous detection range is equal to the number of subcodes within a code period. To extend the unambiguous detection range beyond a single-code period, develops a novel relationship between the polyphase P4 code and the robust symmetrical number system (RSNS) where the P4 phase values within the code period match the symmetrical residues within an RSNS sequence. By transmitting $N \geq 2$ coprime P4 code periods, the unambiguous range is extended by considering the paired values from each sequence. With this new approach, the unambiguous range is extended to the greatest length of combined coprime phase sequences that contain no repeated paired terms. The flexibility of the RSNS allows the unambiguous range to be extended using a fewer number of subcodes within each code period. The combined phase sequences also have an inherent integer Gray code property to control range detection errors. Examples are shown to demonstrate the feasibility of the approach and to compare the unambiguous detection range to that of a single P4 code period.

1 Introduction

Continuous waveform (CW) radar systems have a superior low probability of intercept (LPI) performance over pulse train radar systems because of their low-average power transmitted (e.g. 1 W) and their use of pulse compression techniques. Note that we extend the concept of pulse compression to CW (nonpulsed) waveforms since the techniques are similar and the objectives are the same. Since pure CW waveforms cannot resolve the target’s range, periodic modulation techniques are used, such as frequency-modulated CW (FMCW), frequency-shift keying (FSK), noise modulation, phase-shift keying (PSK), as well as hybrids of these techniques [1]. Owing to the advances in high-speed processing and direct digital synthesis modules, the use of PSK techniques in CW radar is highly advantageous. CW radar systems that transmit and receive PSK signals can have small range resolution cells and are ideally suited for many sensor applications for situational awareness, including over-the-horizon-radar systems and multiple-input multiple-output configurations.

Polyphase coding refers to PSK modulation of the CW carrier. Polyphase sequences are of finite length with $N_c$ subcodes, each with a discrete phase value to modulate the CW carrier. The number of subcodes is taken from an alphabet of size $N_c \geq 2$, which is also the processing gain (PG) of the radar excluding any post-detection integration. The polyphase code period is $T = N_c \nu_0$, where $\nu_0$ is the size of each subcode which determines both the 3 dB bandwidth of the waveform $B = 1/\nu_0$ and the range resolution $\Delta R = c \nu_0/2$. The unambiguous range is limited by the number of subcodes within a code period as $R_u = N_c \Delta R$. Increasing the number of phase subcodes in the sequence results in a greater PG in the receiver or equivalently a larger signal-to-noise ratio (SNR).

With a CW polyphase waveform, the matched filter in the receiver is a coherent, range–Doppler correlation processor that performs a cross correlation between the received $N_r$ returned code periods from the target and $N_r$ reference code periods where each reference code period is the complex conjugate of the transmitted polyphase code [2]. To reduce the periodic ambiguity sidelobe levels the $N_r$ cross correlation output values can be added together. When the polyphase signals are returned and have an impressed Doppler shift, the correlation process used in the receiver compression operation is not perfect, resulting in a certain amount of correlation loss because of the phase shifts across the code period $T$.

One of the most important PSK codes used in CW radar is the P4 code [3, 4]. The P4 code consists of discrete phases of a linear chirp waveform taken at specific time intervals. It is derived by converting a linear FMCW to baseband using a local oscillator on one end of the frequency sweep and sampling the inphase ($I$) and quadrature ($Q$) video at the Nyquist rate. The P4 phase steps exhibit a parabolic distribution that is symmetrical. The P4 is also a Doppler tolerant perfect code in that it exhibits a perfect periodic autocorrelation function – namely zero autocorrelation sidelobes [1].

Although the P4 polyphase modulation can serve as a transmission waveform for a CW radar system, there are several limitations. Most significantly, the unambiguous
Each subcode with phase code periods can also have a small number of subcodes. Owing to the flexibility offered by the RSNS, the modular errors in the detected target’s range that might occur makes it particularly attractive for controlling any possible sequences have an inherent integer Gray code property that subcode period. In addition, the combined RSNS phase Ru

range of combined coprime phase sequences that contain no subcodes within a single-code period to the greatest length modulus, the unambiguous range is extended by code sequences that correspond to an RSNS coprime integer within an RSNS sequence is called a symmetrical subcode period. The RSNS is a modular system consisting of \( N \) integer \( m_i \) from the set \( m_1, m_2, \ldots, m_N \) [5, 6]. Each integer within an RSNS sequence is called a symmetrical residue and corresponds to a single subcode within the phase code sequence. By using \( i = 1, 2, \ldots, N \) \( N \geq 2 \) P4 code sequences that correspond to an RSNS coprime modulus, the unambiguous range is extended by considering the paired values from each sequence. The unambiguous range is extended from the number of subcodes within a single-code period to the greatest length of combined coprime phase sequences that contain no repeated paired terms which is called the RSNS dynamic range \( M_{\text{RSNS}} \). Collectively processing \( N \geq 2 \) symmetrical residue P4 phase code sequences, the unambiguous target detection range is extended from \( R_u = cT/2 = ct_bN_c/2 \) for an individual code to \( R_u = ct_bM_{\text{RSNS}}/2 \) where \( t_b \) is the subcode period. In addition, the combined RSNS phase sequences have an inherent integer Gray code property that makes it particularly attractive for controlling any possible errors in the detected target’s range that might occur. Owing to the flexibility offered by the RSNS, the modular code periods can also have a small number of subcodes.

### 2 CW phase modulation radar

In polyphase CW radar, the phase-shifting operation is performed in the radar’s transmitter, with the timing information generated from the receiver–exciter. The transmitted complex signal can be written as \([1]\)

\[
s(t) = Ae^{j(2\pi f_c t + \phi(t))}
\]

where \( A \) is the signal amplitude, \( f_c \) is the carrier frequency and \( \phi(t) \) is the time-dependent phase modulation. For a code period \( T \), the CW signal is shifted in phase every subcode with each code period consisting of \( k = 1, \ldots, N \) subcodes. Each subcode with phase \( \phi_k \) has a duration of \( t_b \). For a polyphase sequence, the code period is \( T = N_c t_b \) \( (2) \).

If \( \text{cpp} \) is the number of cycles of the carrier frequency per subcode, the bandwidth \( B \) of the transmitted signal is

\[
B = \frac{f_c}{\text{cpp}} = \frac{1}{t_b}.
\]

The return signal from the target \( x(t) \) can be written as

\[
x(t) = \eta Ae^{j(2\pi f_c t + \phi(t) + \phi_k(t - \tau))}
\]

where \( \eta \) is the amplitude attenuation coefficient of the received signal because of the target scattering and the propagation path loss. The roundtrip delay \( \tau \) for a target at range \( R \) is \( \tau = 2R/c \), where \( c \) is the speed of light in free space. The Doppler frequency \( \nu \) owing to the target motion is \( \nu = 2V/\lambda \) where \( \lambda \) is the wavelength and \( V \) is the target’s relative radial velocity.

In Fig. 1, a range–Doppler correlation receiver for zero Doppler offset is illustrated \([2]\). The received waveform from the target is processed by a filter matched to a subcode duration \( t_b \). A phase detector then detects the phase of each subcode. The detected output signal is then sent through a tapped delay line where each delay \( D \) is \( t_b \). Instead of using one reference code period, the return signal from the target with \( N_r \) code periods is correlated using a range–Doppler correlator that contains a cascade of \( N_r \) copies of the \( N_c \) reference code periods. To reduce the sidelobe structure further, a weighting function \( C_i \) can be added. To compute the entire range–Doppler ambiguity space, the correlation outputs from each subcode delay are multiplied by \( q^2 = e^{j2\pi \Delta \nu t_b} \) for \( \nu = \Delta \nu \) where \( k \) ranges from 0 to \( N_c N_r - 1 \). For \( \nu = 2\Delta \nu \), the output of the previous \( \nu = \Delta \nu \) operation is again multiplied by \( q^2 = e^{j2\pi \Delta \nu t_b} \) and so on for the entire ambiguity space.

In general, the larger the PG the greater is the SNR improvement in the signal processing. If the radar signal processing input SNR is \( \text{SNR}_{i} \) and the radar signal processing output SNR is \( \text{SNR}_{o} \) then

\[
PG = \frac{\text{SNR}_o}{\text{SNR}_i}
\]

The PG for a polyphase code is equal to the time-bandwidth product

\[
PG = T(1/t_b) = (N_c t_b)/t_b = N_c
\]

and is equal to the number of subcodes within a code period \([1]\).

### 3 P4 Polyphase code

The P4 polyphase code is conceptually derived by converting a linear frequency modulation waveform to baseband by using a synchronous local oscillator that is offset in the I and Q detectors. The sampling of I and Q video at the Nyquist rate yields the polyphase code P4 \([4]\). The P4 consists of the discrete phases of the linear chirp waveform taken at specific time intervals and exhibits the same range–Doppler coupling associated with the chirp waveform. However, the peak sidelobe levels are lower than those of the unweighted chirp waveform. Various weighting techniques can be applied to reduce the sidelobe
levels further. The phase sequence of a P4 signal is given by

$$f_k = p N_c (k - 1)^2 - p (k - 1)$$

where \(k = 1, \ldots, N_c\) is the subcode index and \(N_c\) is the PG. The discrete phase values for the P4 code for \(N_c = 64\) are shown in Fig. 2.

4 Robust symmetrical number system

The RSNS is a modular system consisting of \(N \geq 2\) integer sequences with each sequence associated with a coprime modulus \(m_i\), \(i = 1, \ldots, N\). Owing to the presence of ambiguities, the set of integers within each RSNS sequence do not form a complete residue system [6]. The ambiguities within each modulus sequence are resolved by the use of additional moduli and considering the vector of paired integers from all \(N\) sequences. The RSNS is based on the sequence

$$RS'_m = [0, 1, 2, \ldots, m_i - 1, m_i, m_i - 1, \ldots, 2, 1]$$

To form the \(N\)-sequence RSNS, each term in (8) is repeated \(N\) times in succession. The integers within one folding period of a sequence are then

$$RS_{m_i} = [0, 0, \ldots, 0, 1, 1, \ldots, 1, m_i - 1, \ldots, m_i - 1, \ldots, 1, \ldots, 1]$$

This results in a periodic sequence where each code period consists of

$$N_{RSNS} = 2Nm_i$$

subcodes [5], which is also the period of the sequence. Each sequence corresponding to \(m_i\) is also right (or left) shifted by \(s_i = i - 1\) places. The chosen shift values \(\{s_1, s_2, \ldots, s_N\}\) must form a complete residue system modulo \(N\). The shift values \(s_i\) for each sequence do not affect the dynamic range \(M_{RSNS}\) but do make a difference in the location of the beginning position of \(M_{RSNS}\), \(h\), and the ending position, \(h + M_{RSNS} - 1\).

After choosing the beginning position \(h\), it is useful to know the symmetrical residues at this point in order to align them for each sequence. If each sequence is extended periodically with period \(2Nm_i\) as \(RS_{m_i,h + 2Nm_i} = RS_{m_i,h}\)
where \( n \in 0, \pm 1, \pm 2, \ldots \), then \( RS_{m_i} \) is called a symmetrical residue of \((h + n2Nm_i)\) modulo \(2Nm_i\). Since each period consists of \(2Nm_i\) integers, the symmetrical residues are determined by first subtracting off an integer number of \(2Nm_i\) integers as [7]

\[
n_i = h - \frac{h}{2Nm_i} \cdot 2Nm_i
\]

This value is then used to find the symmetrical residue \(RS_{m_i}\) as

\[
RS_{m_i} = \begin{cases} 
\frac{n_i - s_i}{N} & , s_i \leq n_i \leq Nm_i + s_i + 1 \\
2Nm_i + N - n_i + s_i - 1 & , Nm_i + s_i + 2 \leq n_i \leq 2Nm_i + s_i - 1
\end{cases}
\]

The calculation of \(M_{RSNS}\) is a function of \(N\) and the chosen \(m_i\). A closed-form solution for computing \(M_{RSNS}\) for \(N = 2\) moduli is reported in [8], and summarised as follows.

For \(m_1 \geq 3\) and \(m_2 = m_1 + 1\)

\[
M_{RSNS} = 3(m_1 + m_2) - 6 = 6m_1 - 3
\]

For \(5 \leq m_1 < m_2\) and \(m_2 \leq m_1 + 2\)

\[
M_{RSNS} = 4m_1 + 2m_2 - 5
\]

For \(5 \leq m_1 < m_2\) and \(m_2 \geq m_1 + 3\)

\[
M_{RSNS} = 4m_1 + 2m_2 - 2
\]

A closed-form solution for \(N = 3\) moduli of the form \(2^z - 1, 2^z, 2^z + 1\) is

\[
M_{RSNS} = 3 \cdot 2^{m_1^2 + 15/2m_1 + 7}
\]

where \(z\) is any integer and \(m_1 \geq 3\) [6]. An efficient algorithm for computing \(M_{RSNS}\) and its position for any general set of moduli is reported in [9].

Let \(X_3\) be the vector of \(N\) paired integers from each sequence within the RSNS at \(h\) where \(h\) is the beginning position of the vector \(X_3\). In Table 1, the symmetrical residues for an \(N = 3\) RSNS system with \(m_i = [3 \ 4 \ 5]^T\) and right shift \(s_i = [0, 1, 2]^T\) are shown. For this example, from (16) the RSNS dynamic range is \(M_{RSNS} = 43\), and the position begins at \(h = 61\) with the vector \(X_6 = [2 \ 4 \ 1]^T\). The set of integers that lie within the dynamic range \(M_{RSNS} = 43\) contain no ambiguities. Note in Table 1 the integer Gray code property where any code transition results in just one integer changing value by \(\pm 1\). Also shown is the bin index \(a\), which runs from 0 to 42 (total 43) that will be used to refer to the range bin position.

### Q1

#### 5 Robust symmetrical residue-P4 phase code

Owing to the symmetrical distribution of the P4 phase values, the RSNS symmetrical residues within a modulus can be related to a P4 code sequence. The RSNS symmetrical residues can be folded into the P4 phase sequence (9) by associating the symmetrical residues \(RS_{m_i,k^c}\) with the P4 subcode phases. The phase index \(k^c\) runs from 1, \(\ldots\), \(N_{c_{RSNS}}\), where \(N_{c_{RSNS}}\) is the number of RSNS subcodes within one code period. The symmetrical residue-P4 phase sequence for modulus \(m_i\) is given by

\[
\phi_{m_i,k^c} = \left[ \frac{\pi}{2m_i} \cdot (RS_{m_i,k^c} - m_i) \right]^2 - \frac{\pi}{2} m_i
\]

and from (10) \(N_{c_{RSNS}} = 2m_iN\), where \(N\) is the number of modular multiphase waveforms transmitted. For example, if \(N = 2\) and the first modulus in the sequence is \(m_i = 4\), then \(N_{c_{RSNS}} = 16\). From (9) the symmetrical residue integers within the modulus are \(RS_{m_i = 4,k^c} = [0, 0, 1, 1, 2, 2, 3, 3, 4, 4, 3, 3, 2, 2, 1, 1]\) which consists of \(N_{c_{RSNS}} = 16\) integers. From (17) the phase sequence in radians is \(\phi_{m_i = 4,k^c} = [0, 0, -2.75, -2.75, -4.71, -4.71, -5.89, -5.89, -6.28, -5.89, -5.89, -4.71, -4.71, -2.75, -2.75]\). We now let \(N_{c}\) be the number of subcodes or processing gain, within a P4 sequence (7). The number of subcodes in a P4 sequence is related to the number of subcodes within a symmetrical residue-P4 sequence by

\[
N_{c} = \frac{N_{c_{RSNS}}}{N} = 2m_i
\]

Consequently, the number of P4 subcodes \(N_{c_1}\) for \(m_i = 4\) is

\[
N_{c_1} = \frac{N_{c_{RSNS}}}{N} = 8
\]

Recall that \(cpp\) represents the number of carrier frequency cycles per subcode. The \(cpp\) value for a P4 subcode is \(N\) times that of a symmetrical residue-P4 subcode. That is, for the P4, the subcode period is

\[
t_P = \frac{cpp}{f_c}
\]

and for the symmetrical residue-P4, the subcode period is

\[
t_P = \frac{cpp}{N f_c}
\]

From (20) and (21), we have

\[
t_P = N t_p
\]

Note that from (18) the symmetrical residue-P4 code period is

\[
T_t = t_P N_{c_{RSNS}} = t_P N_{c_1} N
\]

For example, in Fig. 3 we see that the phase sequence for the symmetrical residue-P4 for \(m_i = 16, N = 2\) and \(N_{c_{RSNS}} = 64\) is actually the same as the P4 phase code sequence using \(N_{c_1} = 32\).
6 Radar application of the robust symmetrical residue-P4 phase code

The block diagram of the CW radar using the symmetrical residue-P4 phase code modulation is shown in Fig. 4. In the transmitter, the first step is to generate and store the sequence values \( RS_{m_i,k} \) for each modulus. Then, a direct digital synthesiser uses each residue sequence \( RS_{m_i,k} \) to generate the subcode phase values \( f_{m_i,k} \) according to (17) for each modulus. Each subcode corresponding to \( RS_{m_i,k} \) has a length of \( t_{c_i} \). Together the \( N_{RSNS} \) subcodes have a code period of \( T_c \). To detect the target’s range unambiguously, each coprime sequence must have \( \hat{M}_{RSNS} \) subcodes. Each sequence is amplified and transmitted in succession.

Upon reception, the signal is amplified and downconverted to an intermediate frequency compatible with an available analogue-to-digital (ADC) converter technology. The output of the ADC is processed by a moving target indication (elliptic) filter to remove the clutter, and then the phase of each subcode is detected. The output of the phase detector is processed by a phase code compressor that is followed by a non-coherent post-detection integration (PDI) process. The output of the PDI is sent to a constant false alarm rate processor to detect and save the range bin of the target for that modulus sequence. This series of steps is performed for each symmetrical residue-P4 phase code sequence, and the detected target’s range bin for each code is sent to an algorithm to resolve the target’s true range after all \( N \) symmetrical residue sequences are obtained [10].

To illustrate the concept, the previous example is worked using \( N = 3 \) RSNS moduli with \( m_1 = 3 \), \( m_2 = 4 \) and \( m_3 = 5 \). For these moduli, the dynamic range from (16) is \( M_{RSNS} = 43 \). The transmitted signal is shown in Fig. 5. Each sequence has a length equal to \( M_{RSNS} \) subcodes. For the first modulus, \( m_1 = 3 \), there are four symmetrical residues:

\[
\begin{array}{cccccc}
\end{array}
\]

sequence for $m$ code periods needed to cover $\times$ subcodes is 2 residues are 0, 1, 2, 3 and 4. The required number of $2$ residues are 0, 1, 2, 3, 4 and 5. The number of subcodes is sequence (multiple code periods) is transmitted signal. The number of subcodes within each Fig. 5, the reference signals start from the beginning of the calculate the code compression output. Referring again to P4 subcode phase values using $\hat{N}_{ci}$ Fig. 6a, the symmetrical residues for $m_1 = 3$, $m_2 = 4$ and $m_3 = 5$ with $M_{RSNS} = 43$ are shown. Also, the phase sequences from each modular waveform are plotted in Fig. 6b. Since $RS_{m_i,h+n2Nm_i} = RS_{m_i,h}$ where $n \in \{0, \pm 1, \pm 2, \ldots \}$, the phase sequences are periodic with $\phi_{m_i,k'} = \phi_{m_i,k}$. Using all sequences, the paired terms are mapped to a specific range bin $a$. Continuing the example for $m_1 = 3$, $m_2 = 4$ and $m_3 = 5$, we show the robust symmetrical residue-paired values and the corresponding ranges in Table 1. The signal bandwidth is 3 MHz and the subcode period is $\hat{t}_b = t_b/N = 0.33 \mu s$. For the range resolution shown the new unambiguous range using the symmetrical residue-P4 modulation is

$$R_{RSNS} = \frac{c\hat{M}_{RSNS}\hat{t}_b}{2}$$

For this example, the maximum unambiguous range is $R_{RSNS} = 2150 m$ and the range resolution is $\Delta R = ct_b/2 = 50 m$.

An example of the target detection for $m_1 = 3$, $m_2 = 4$ and $m_3 = 5$ is illustrated in Fig. 7. The target is in range bin $a = 1$. From Table 1, the corresponding range of the detected target is between 250 and 300 m. First, the phase code signal for $m_1 = 3$ (top) is compressed giving the symmetrical residue $RS_3 = 2$. The process is the same for the modular waveforms $m_2 = 4$ and $m_3 = 5$ and the symmetrical residues containing the target are $RS_4 = 3$ and $RS_5 = 1$. The three robust symmetrical residues are paired as [2 3 1] and must be converted to a more convenient, for example, binary number and can be computed with a look up table or using the algorithm as described in [10].

### 7 Practical considerations

To examine the practical advantage of the RSNS P4 approach, we note that for a single P4 code period, the unambiguous range for a single modulus $m_i$ is limited to

residues within the sequence: 0, 1, 2 and 3. The sequence code period corresponding to $m_1$ needs $N_{i_{RSNS}} = 2Nm_1 = 2 \times 3 \times 3 = 18$ subcodes. For $m_2 = 4$, the symmetrical residues are 0, 1, 2, 3 and 4. The required number of subcodes is $2 \times 3 \times 4 = 24$. For $m_3 = 5$, the symmetrical residues are 0, 1, 2, 3, 4 and 5. The number of subcodes is $2 \times 3 \times 5 = 30$. As shown in Fig. 5, the beginning of each sequence for $m_1 = 3$, $m_2 = 4$ and $m_3 = 5$ are $k' = 8$, $k' = 13$ and $k' = 30$, respectively, since, from (11) and (12), $X_{61} = [2 4 1]^T$.

Each reference code must have a length equal to the code period $T_i$ for each modular waveform in order to correctly calculate the code compression output. Referring again to Fig. 5, the reference signals start from the beginning of the transmitted signal. The number of subcodes within each sequence (multiple code periods) is $M_{RSNS}$ The number of code periods needed to cover $M_{RSNS}$ is

$$N_{p,m_i} = \frac{M_{RSNS}}{2m_iN}$$

Sending 43 subcodes for $m_1 = 3$ requires $N_{p,3} = 43/18 = 2.4$ code periods. For $m_2 = 4$ and $m_3 = 5$,
With the RSNS-P4 waveform concept the range can be extended to $R_{\text{RSNS}} = c_t M_{\text{RSNS}}/2$. To compare the detection range of the RSNS-P4 waveform with the corresponding single P4 code sequences, we note that the average signal power $P_{\text{CW}}$ and the maximum detection range $R_{\text{max}}$ are related as [1]

$$R_{\text{max}} = \left( \frac{P_{\text{CW}} G_t G_r}{(4\pi)^2 k_B T_0 T_r R_r (\text{SNR}_{\text{SNR}} / PG)^2} \right)^{1/4}$$

a With $m_1 = 3$, $m_2 = 4$ and $m_3 = 5$ with $M_{\text{RSNS}} = 43$

b Their phase values
where $k_B = 1.38 \times 10^{-23}$ J/K (Boltzman’s constant), $T_0 = 290$ K is the ambient noise temperature, $F_R$ is the receiver noise factor, $B_{Ri}$ is the radar receiver’s input bandwidth in Hz, $G_t$ and $G_r$ are the transmitting and receiving antenna gains, $L (L \geq 1)$ a factor to account for losses and $s$ is the target’s radar cross section in square metre. Propagation and loss factors have been omitted, since they do not directly affect the comparison.

The maximum resolvable detection range is limited by the unambiguous range. That is, the radar may be able to detect targets beyond $R_u$ of the waveform, but there are ambiguities that must be resolved, commonly by using coincidence ranging [11, 12]. In Fig. 8, the maximum detection range is plotted as a function of the required CW power using $N = 3$ for $m_1 = 3$, $m_2 = 4$, and $m_3 = 5$ with a constant $\text{SNR}_{R_u} = 13$ dB, $B_{Ri} = 3$ MHz, $(t_b = 0.333 \mu s)$, $G_t = G_r = 33$ dB, $f_c = 3$ GHz, $\lambda = 0.1$ m, $\sigma = 100$ m$^2$ and $T_0 = 290$ K, a loss factor of $L = 4/3$ and $F_R = 5$ dB. For comparison, the unambiguous range $R_u$ is shown for each P4 code used individually with the corresponding $N_{ci}$ subcodes. For the P4 code, from (18), $N_{c1} = 18/3 = 6$, $N_{c2} = 8$, and $N_{c3} = 10$ for $m_1 = 3$, $m_2 = 4$ and $m_3 = 5$, respectively. The individual P4 unambiguous ranges are $R_{u1} = 3 \times 10^8 \times 10^{-6} \times 6/2 = 900$ m, $R_{u2} = 1200$ m and $R_{u3} = 1500$ m, respectively; all are less than what is achieved using the $N = 3$ RSNS-P4 waveform, which is $R_{RSNS} = cM_{RSNS}/2 = 2150$ m. Note that to achieve this additional range, an increase in CW power is required as expected.

Detecting the target’s correct range without error is a significant advantage of the RSNS encoding of the P4 waveform. Examination of Table 1 shows that a range bin error of $+1$ in any one coprime sequence (e.g. because of noise), may cause the resolved target’s range to be off by only one range bin. The target’s velocity also presents a limitation on the transmitted waveform. In order that the target does not transition a subcode or range bin until the $N_{cRSNS}$ subcodes are reflected from the target, the target’s maximum allowable relative radial velocity must satisfy from (20) and (21)

$$\Delta R > (t_bM_{RSNS}) V_r$$  \hspace{1cm} (27)

or

$$N_{cRSNS} < \frac{c}{2V_r}$$  \hspace{1cm} (28)

For the example shown, if the velocity is Mach 2 (680 m/s), then the product $N_{cRSNS} < 22.06 \times 10^4$. Note that (28) provides considerable flexibility in the waveform design.
allowing a large unambiguous range using only a few coprime sequences. This adds considerably to the LPI nature of the waveform.

8 Summary and conclusions

It was demonstrated that the RSNS can be used in the construction of P4 polyphase waveforms. Using multiple RSNS moduli significantly extends the unambiguous range of the P4 modulation beyond a single code period. In addition, all of the desirable properties of the P4 code are maintained such as Doppler tolerance and periodic ambiguity sidelobe performance [1]. Also, when using the RSNS mapping, the number and choice of moduli is flexible. Consequently, the number of subcodes within a code period can be made significantly smaller resulting in a smaller digital correlation processor. In addition, the combined RSNS phase sequences have an inherent integer Gray code property that makes it particularly attractive for controlling any possible errors in the detected target’s range that might occur. The limitations on the product $NM$ show that a considerable number of symmetrical residue-P4 waveforms can be designed and implemented. The RSNS mapping allows control of the maximum unambiguous range and range resolution over a wide parameter space, limited only by the capability of the hardware. With components such as direct digital synthesisers and digital receivers, the waveform can be reconfigured for different code lengths adding to the LPI characteristics of the waveform.

We note that the unambiguous range of a CW Frank code and the P2 (not a perfect code) can also be extended in a similar manner using a residue number system (RNS) mapping because of the saw-tooth waveform characteristic of the phase distribution within a code period [13]. The residue-Frank phase code however, does not have an integer Gray code property and, as such, if the detected target’s range bin in one of the transmitted sequences is incorrect, a very large range error will occur. For the P1 and P3 polyphase (perfect) codes, a number theoretic transform is not obvious. We also note that the Doppler responses of the P3 and P4 codes have much lower peak sidelobes (secondary maxima) than the Frank, P1 and P2 codes and have comparable image lobes that are because of the polyphase codes being derived from a Nyquist rate sampling of the linear chirp phase characteristics [14].
