Microwave Devices & Radar

LECTURE NOTES
VOLUME III

by Professor David Jenn

Contributors: Professors F. Levien, G. Gill, J. Knorr, P. Pace and J. Lebaric
Noise Power Spectral Density

A “noise signal” in the time domain is denoted as \( n(t) \) and its power spectral density (or simply power spectrum) is \( S_N(f) \) (i.e., therefore \( n(t) \leftrightarrow S_N(f) \)). White noise is zero mean and has a constant power spectrum

\[
S_N(f) \equiv \frac{N_o}{2} = kT
\]

The factor of 1/2 is typically added because the noise power is defined only for positive frequencies, but the power spectral density frequently occurs in integrals with \(-\infty < f < \infty\) or \(-B < f < B\).

The noise power in a band of frequencies between \( f_1 \) and \( f_2 \) (\( \Delta f = f_2 - f_1 \)) is the integral of the power spectral density:

\[
N = \int_{f_1}^{f_2} \left( \frac{N_o}{2} \right) df = \frac{n_o \Delta f}{2}
\]

The total noise power is infinite since

\[
N = \int_{-\infty}^{\infty} \left( \frac{N_o}{2} \right) df = \infty
\]

and thus true white noise does not exist. It is a useful model for situations where the noise bandwidth is so large that it is out of the range of the frequencies of interest.
Matched Filters (1)

Bandwidth tradeoff for filters:

large bandwidth $\rightarrow$ signal fidelity, large noise
small bandwidth $\rightarrow$ signal distorted; low noise

The optimum filter characteristic depends on the waveform. It is referred to as the matched filter. It maximizes the peak signal to mean noise power ratio.

$$y(t) = s(t) * h(t) = \int_{0}^{t} s(\tau) h(t - \tau) d\tau$$

or,

$$Y(\omega) = H(\omega)S(\omega)$$

What $H(\omega)$ (also expressed as $H(f)$) will maximize the output SNR?
Matched Filters (2)

Assume a time limited signal that has a maximum output at time $t = t_1$. The maximum at the output is

$$y(t_1) = \frac{1}{2\pi} \int_{-\infty}^{\infty} S(\omega)H(\omega)e^{j\omega t_1} d\omega$$

$$= \int_{0}^{t_1} s(\tau)h(t_1 - \tau)d\tau = \int_{0}^{t_1} s(t_1 - \tau)h(\tau)d\tau$$

For a $1\Omega$ load the instantaneous output power is $S = y^2(t)$. Consider a differential band of frequencies between $f$ and $f + df$. The noise spectra at the input and output are $S_N(f)$ and $Y_N(f)$, respectively. Therefore

$$Y_N(f) = S_N(f)H(f)$$

Mean-squared noise power at the output:

$$N = \sigma_N^2 = \left\langle \int_{-\infty}^{\infty} |Y_N(f)|^2 df \right\rangle = \left\langle \int_{-\infty}^{\infty} |S_N(f)H(f)|^2 df \right\rangle$$
The noise power spectral density for white (Gaussian) noise is

\[ N_o(f) = 2\langle |S_N(f)|^2 \rangle = k T_0 \equiv N_o \]

The noise power at the output is

\[ \sigma^2_N = \frac{1}{2} \int_{-\infty}^{\infty} |H(f)|^2 N_o(f) df = \int_{0}^{\infty} |H(f)|^2 N_o df \]

From Parseval's theorem:

\[ \sigma^2_N = \frac{N_o}{2} \int_{-\infty}^{\infty} h^2(t) dt \]

so that

\[ \text{SNR} = \frac{\left| \int_{0}^{t_1} s(t_1 - \tau)h(\tau)d\tau \right|^2}{\int_{-\infty}^{\infty} \left| S(\omega) e^{j\omega t_1} H(\omega) d\omega \right|^2} = \frac{\left| \int_{-\infty}^{\infty} S(\omega) e^{j\omega t_1} H(\omega) d\omega \right|^2}{\pi N_o \int_{-\infty}^{\infty} |H(\omega)|^2 d\omega} \]

Schwartz inequality

\[ \left| \int s(x)h(x)dx \right|^2 \leq \left| \int s(x)dx \right|^2 \left| \int h(x)dx \right|^2 \]
Matched Filters (4)

Note that \( s(t) \) and \( h(t) \) are real

\[
\text{SNR} \leq \frac{\int_0^{t_1} s^2(t_1-t)dt \int_{-\infty}^{\infty} h^2(t)dt}{\frac{N_o}{2} \int_{-\infty}^{\infty} h^2(t)dt} = \frac{\int_{-\infty}^{\infty} \left| S(\omega)e^{j\omega t_1}\right|^2 d\omega \int_{-\infty}^{\infty} \left| H(\omega)\right|^2 d\omega}{\pi N_o \int_{-\infty}^{\infty} \left| H(\omega)\right|^2 d\omega}
\]

The maximum will occur when the equality holds

\[
h(t) = \begin{cases} \alpha s(t_1-t), & t < t_1 \\ 0, & t > t_1 \end{cases} \quad \text{or} \quad H(\omega) = \alpha \left[ S(\omega)e^{j\omega t_1}\right]^* = \alpha S^*(\omega)e^{-j\omega t_1}
\]

where \( \alpha \) is a constant. This is the matched filter for the signal \( s(t) \). The maximum SNR is

\[
\text{SNR} \leq \frac{\int_0^{t_1} s^2(t)dt}{\frac{N_o}{2}} = \frac{2E}{N_o}
\]

The signal energy is \( E \equiv \int_0^{t_1} s^2(t)dt \) (Note: in general \( E \equiv \int_{-\infty}^{\infty} s^2(t)dt \).)

Matched Filters (5)

In the frequency domain:
\[ H(\omega) = \alpha \left[ S(\omega)e^{j\omega t_1} \right]^* = \alpha S^*(\omega)e^{-j\omega t_1} \]

(This is Equation [5.15] in Skolnik when \( \alpha \) is replaced with \( G_a \).) Some important points:

1. The matched filter characteristics depend on the waveform.
2. It doesn't matter what the waveform is, if a matched filter is used in the receiver the SNR=2E/No
3. \( t_1 \) may be very large, which implies long delays and consequently a physically large filter.
4. The output of the matched filter is the autocorrelation function of the input signal
\[ y(t) \equiv R(t-t_1) = \int_{-\infty}^{\infty} s(\tau)s(t_1-t+\tau)d\tau \]

Example: Find the matched filter characteristic for a pulse of width \( \tau \) and amplitude 1
\[ p_\tau(t) \leftrightarrow S(\omega) = \tau \text{sinc}(\omega \tau / 2) \]
Matched Filters (6)

The matched filter characteristic for this waveform is

\[ H(\omega) = \alpha S^*(\omega)e^{-j\omega t_1} = \alpha \tau \text{sinc}(\omega \tau / 2) e^{-j\omega \tau} \]

The choice of \( t_1 = \tau \) is somewhat arbitrary. The output signal spectrum is

\[ Y(\omega) = S(\omega)H(\omega) = \alpha \tau^2 \text{sinc}^2(\omega \tau / 2)e^{-j\omega \tau} \]

The output waveform is the inverse Fourier transform: a time delayed triangle. The matched filter is realized using a tapped delay line.

The output signal builds as the input signal arrives at more taps. After time \( \tau \) (end of the pulse) some taps are no longer excited and the output signal level decays. After \( 2 \tau \) none of the taps are excited.
Matched Filters (7)

The signal energy is

\[ E = \int_0^\tau p_\tau^2(t) dt = \tau \]

and the impulse response of the filter is

\[ h(t) = \alpha p_\tau(t) \]

The signal to noise ratio is

\[
\text{SNR} = \frac{\left| \int_0^\tau p_\tau(t_1 - \tau) h(\tau) d\tau \right|^2}{\frac{N_o}{2} \int_0^\tau h^2(\tau) d\tau} = \frac{\alpha^2 \tau^2}{\frac{N_o}{2} \alpha^2 \tau} = \frac{2E}{N_o}
\]

as expected for a matched filter.
Complex Signals

A narrowband signal can be cast in the following form: (see Vol. II, p.25)

\[ s(t) = a(t)\cos(\omega_c t + \Phi(t)) \]

or, in terms of in-phase \((I)\) and quadrature \((Q)\) components

\[ s(t) = I(t)\cos(\omega_c t) - Q(t)\sin(\omega_c t) \]

where

\[ I(t) = a(t)\cos(\Phi(t)) \]
\[ Q(t) = a(t)\sin(\Phi(t)) \]

Define the complex envelope of the signal as

\[ u(t) = I(t) + jQ(t) \]

Thus the narrowband signal can be expressed as a complex signal (also called an analytic signal)

\[ s(t) = \text{Re}\left\{u(t)e^{j\omega_c t}\right\} \]

It is sufficient to deal with the complex envelope of a signal (to within a phase shift and constant factor).
Ambiguity Function (1)

Matched filter output signal, $y(t)$, in terms of the complex envelope, $u(t)$

$$y(t) = \frac{\alpha}{2} e^{\frac{j}{2} \omega_c t_1} \int_{-\infty}^{\infty} u(\tau) u^* (\tau - t + t_1) d\tau$$

If there is a Doppler frequency shift

$s(t) = \text{Re} \left\{ u(t) e^{j \omega_d t} e^{j \omega_c t} \right\}$

New Envelope

Term

Filter

Signal

Term

This is the ambiguity function

$$|\chi(\tau, \omega_d)| = \int_{-\infty}^{\infty} u(t) e^{j \omega_d t} u^* (t - \tau) dt$$
Ambiguity Function (2)

Since $\tau$ is a time delay, let it be the round trip transit time for range $R, T_R$. Also, express the Doppler frequency in Hertz:

$$|\chi(T_R, f_d)|^2 = \left| \int_{-\infty}^{\infty} u(t) e^{j2\pi f_d t} u^*(t + T_R) \, dt \right|^2$$

A plot of $|\chi|^2$ is called an ambiguity diagram. Typical plot:
Ambiguity Function (3)

Properties of the ambiguity function:

1. Peak value is at $T_R = f_d = 0$ and is equal to $2E$.
2. The function has even symmetry in both $T_R$ and $f_d$.
3. Peaks in the diagram other than at $T_R = f_d = 0$ represent ambiguities. Therefore only a single narrow peak is desired (central “spike”).
4. Region under the curve is equivalent to energy, and is constant

$$\iint |\chi|^2 dT_R df_d = (2E)^2$$

Information available from the ambiguity function:

1. **accuracy**: indicated by the width of the central spike
2. **resolution**: width of the central spike and its closeness to other spikes
3. **ambiguities**: spikes along $T_R$ are range ambiguities; spikes along $f_d$ are velocity ambiguities
4. **clutter suppression**: good clutter rejection where the function has low values
Ambiguity Function (4)

Example (after Levanon): single pulse, $\tau = 2$
Ambiguity Function (5)

Example (after Levanon): pulse train, $\tau = 0.2$ and $T_p = 1$
Range Accuracy (1)

The range accuracy depends on the pulse leading edge threshold; that is the time at which we consider the pulse to have arrived.

The measured pulse (i.e., pulse with noise) crosses the threshold too soon by an amount $\Delta T_R$. This is equivalent to a range error. The slope of the measured pulse in the vicinity of the threshold is

$$\text{slope} \approx \frac{n(t)}{\Delta T_R}$$

The slope of the uncorrupted pulse is

$$\text{slope} \approx \frac{A}{t_r}$$
Range Accuracy (2)

Assume that the slopes are approximately equal

\[
\frac{A}{t_r} \approx \frac{n(t)}{\Delta T_R} \Rightarrow \Delta T_R \approx \frac{n(t) t_r}{A}
\]

Take expectation of each side

\[
\left\langle \left( \Delta T_R \right)^2 \right\rangle \approx \left( \frac{t_r}{A} \right)^2 \left\langle n^2(t) \right\rangle
\]

\[
\left( \Delta T_R \right)^2 \approx \left( \frac{t_r}{A} \right)^2 n^2(t)
\]

\( t_r \) is limited by the IF amplifier bandwidth \( t_r \approx 1 / B \), or

\[
n(t)^2 = N_o B
\]

Therefore the rms range delay error is

\[
\sqrt{\left( \Delta T_R \right)^2} \equiv \delta T_R = \sqrt{\frac{N_o B}{A^2 B^2}} = \sqrt{\frac{N_o}{A^2 B}}
\]
Range Accuracy (3)

Use pulse energy rather than amplitude: \( E = \frac{A^2 \tau}{2} \)

\[ \delta T_R = \sqrt{\frac{\tau}{(2E / N_o)B}} \]

Average the leading and trailing edge measurements

\[ \delta T_R \approx \sqrt{\left(\Delta T_R^2\right)_1 + \left(\Delta T_R^2\right)_2} = \sqrt{2} \sqrt{\Delta T_R^2} \]

Final result, based on a rectangular pulse,

\[ \delta T_R = \sqrt{\frac{\tau}{(2E / N_o)2B}} \]

Skolnik has results for several different pulse shapes in terms of the effective bandwidth of the pulse.
Range Accuracy (4)

General equation for an arbitrary pulse shape:

\[ \delta T_R = \frac{1}{B_e \sqrt{2E / N_o}} \]

where the effective bandwidth of the pulse is defined by (Skolnik uses \( \beta \)).

\[
B_e^2 = \frac{\int (2\pi f)^2 |S(f)|^2 df}{\int |S(f)|^2 df} = \frac{1}{E} \int (2\pi f)^2 |S(f)|^2 df
\]

For a rectangular pulse \( S(f) \propto \text{sinc}(\pi f \tau) \) and with some math (see Skolnik for details)

\[ B_e^2 \approx 2B / \tau \]

Therefore, \( \delta T_R = \sqrt{\frac{\tau}{4BE / N_o}} \) which corresponds to a range error of \( \delta R = \frac{c \delta T_R}{2} \)
Velocity Accuracy

Method of "inverse probability" gives an expression for the rms frequency error:

\[ \delta f = \frac{1}{\tau_e \sqrt{2E / N_o}} \]

\(\tau_e\) is the effective time duration of the pulse defined as

\[ \tau_e^2 = \frac{\int (2\pi t)^2 s^2(t) dt}{\int s^2(t) dt} \]

(Skolnik uses \(\alpha\).) For a rectangular pulse \(\tau_e^2 = (\pi \tau)^2 / 3\) which gives

\[ \delta f = \frac{\sqrt{3}}{\pi \tau \sqrt{2E / N_o}} \]
Uncertainty Relation

There is a tradeoff between range and velocity accuracies: a narrow spectrum and short time waveform cannot be achieved simultaneously. This has been traditionally referred to as the “radar uncertainty principle,” which is a misnomer. The uncertainty relation states that the effective time-bandwidth product must be greater than $\pi$:

$$B_e \tau_e \geq \pi$$

The “poorest” waveform in this sense is the Gaussian pulse for which $B_e \tau_e = \pi$.

Since

$$\delta T_R \delta f = \frac{1}{B_e \tau_e \left(2E / N_o\right)}$$

The uncertainty relation can be written as

$$\delta T_R \delta f \leq \frac{1}{\pi \left(2E / N_o\right)}$$

Accuracies can be made as small as desired by increasing the SNR which, of course, has practical limitations.
Angular Accuracy

Recall that there is a Fourier transform relationship between an antenna’s aperture distribution and the far-field pattern. Therefore the pulse/bandwidth formulas for velocity accuracy can be extended to antenna pointing

\[ \delta \theta = \frac{\lambda}{w_e \sqrt{2E/n_o}} \]

\( w_e \) is the effective aperture width of the antenna

\[ w_e^2 = \frac{\int_{-\infty}^{\infty} (2\pi x')^2 |A(x')|^2 \, dx'}{\int_{-\infty}^{\infty} |A(x')|^2 \, dx'} \]

(Skolnik uses \( \gamma \) and has moved \( \lambda \) from the top formula to the numerator of \( w_e \).) For a uniform amplitude distribution over an aperture of width \( D \), \( w_e^2 = (\pi D)^2 / 3 \) which gives

\[ \delta \theta = \frac{\sqrt{3}}{\pi(D/\lambda) \sqrt{2E/n_o}} = \frac{0.628 \theta_B}{\sqrt{2E/n_o}} \]

where \( \theta_B = 0.88 \lambda / D \) has been used.
Pulse Compression

Short pulses are good for small range resolution, but there are problems in practice:
1. difficult to get high energy on the target unless the short pulses are very high peak power
2. short pulses require very wide bandwidth hardware

Pulse compression refers to several techniques that use “long time” waveforms yet get some of the advantages of “short time” waveforms. Three methods are:
1. Chirp:
   a. most common
   b. simple analog implementation
   c. Doppler tolerant
   d. capable of high pulse compression ratio (PCR)
2. Binary phase codes:
   a. second most common
   b. easy digital implementation (apply separately to I and Q channels)
   c. Doppler sensitive
   d. best for low PCRs
3. Low sidelobe codes:
   a. more difficult to implement; increased complexity
   b. Doppler sensitive
Linear FM Pulse Compression (Chirp)

The carrier frequency of each pulse is increased at a constant rate throughout its duration.

\[ \Delta f \] is the frequency deviation and \( \tau_u \) is the uncompressed pulse width. Low frequencies are transmitted first so they arrive at the receiver first. A filter is used in the receiver that introduces a frequency dependent time lag that decreases at the exact rate at which the frequency of the received echo increases. The front of the pulse is slowed relative to the trailing edge. As a result of the time delay, the pulse “bunches up” and emerges from the filter with a much larger amplitude and shorter width.
Linear FM Pulse Compression (Chirp)

Illustration of the dispersive (frequency dependent) filter:

To see how the original waveform appears to be compressed, we look at its spectrum at the output of the filter. Let:

\[ s(t) = \text{signal into filter (received chirp waveform)} \]
\[ h(t) = \text{matched filter impulse response} \]
\[ g(t) = \text{output signal (compressed pulse)} \]
Linear FM Pulse Compression (Chirp)

Using complex signal notation, the output is:

\[ g(t) = \int_{-\infty}^{\infty} s(\alpha) h^*(t - \alpha) d\alpha \]

The input (chirp) signal is:

\[ s(t) = p_{\tau_u}(t) \exp \left[ j(\omega_c t + \mu t^2 / 2) \right] \]

where

\[ p_{\tau_u}(t) = \text{pulse of width } \tau_u \]

\[ \mu = \text{FM slope constant} = 2\pi B / \Delta f \]

The impulse response of the matched filter is:

\[ h(t) = p_{\tau_u}(-t) \exp \left[ j(-\omega_c t + \mu t^2 / 2) \right] \]

The received chirp signal after mixing (i.e., at IF)

\[ s_{IF}(t) = p_{\tau_u}(t) \exp \left[ j\left(\omega_{IF} - \omega_d\right)t + \mu t^2 / 2\right] \]
Linear FM Pulse Compression (Chirp)

Now perform the convolution

\[ g(t) = \int_{-\tau_u}^{\tau_u} \exp\left[j((\omega_{IF} - \omega_d)\alpha + \mu \alpha^2 / 2)\right] \exp\left[j(\omega_{IF}(t - \alpha) + \mu(t - \alpha)^2 / 2)\right] d\alpha \]

for \( t > 0 \). Evaluate the integral to get

\[ g(t) = (\tau_u - t) e^{j(\omega_{IF} - \omega_d + \mu t / 2)t} \text{sinc} \left( \pi (\tau_u - t)(f_d + Bt / \tau_u) \right) \]

where \( 2\pi B = \mu \tau_u \) has been used. The pulse compression ratio (PCR) is

\[ \text{PCR} = \tau_u \Delta f \equiv \tau_u / \tau \]

Typical values: 100 to 300 (upper limit is about \( 10^5 \)). The peak value of \( g(t) \) occurs at time \( t = -\tau_u f_d / B \). This represents an ambiguity because \( f_d \) is not generally known.
Chirp Filter Output Waveform

The Doppler shift from a moving target causes a time shift in the maximum output of the matched filter. This results in a range error.

Example: \( \Delta f = 1 \text{ MHz} \), PCR=200, \( f_c = 10 \text{ GHz} \)
Improved Range Resolution

To distinguish the two pulses \( \delta t \geq 0 \) which implies

\[
\tau \leq 2\Delta R / c
\]

Pulse compression can improve a radar's resolution
Pulse Compression Example

Example: FM chirp waveform transmits for \( \tau_u = 10 \, \mu s \). What frequency deviation is required to increase the peak SNR by 10 dB at the output of an ideal pulse compression filter?

Definition of PCR: \( \text{PCR} = \tau_u \Delta f = 10 \times 10^{-6} \Delta f \)

The PCR is also the increase in peak SNR. Therefore

\[
(10 \times 10^{-6}) \Delta f = 10 \, \text{dB} = 10 \Rightarrow \Delta f = 1 \times 10^6 = 1 \, \text{MHz}
\]

Range resolution of the uncompressed pulse is

\[
\Delta R = \frac{c \tau_u}{2} = \frac{3 \times 10^8 (10^{-5})}{2} = 1500 \, \text{m}
\]

The compressed pulse width is \( \tau = \frac{\tau_u}{\text{PCR}} \) and the resolution is

\[
\Delta R = \frac{c \tau}{2} = \frac{3 \times 10^8 (10^{-6})}{2} = 150 \, \text{m}
\]
Chirp Complications

Chirp introduces a slight Doppler frequency ambiguity. The radar cannot distinguish between an intended frequency shift and an induced Doppler shift.

The chirp filter output for each pulse is a sinc function. For a train of pulses the sinc functions overlap and time sidelobes from a strong target can mask a weak target (dB scale shown).

The solution is to use phase weighting (i.e., nonlinear FM).
Digital Pulse Compression

Digital pulse compression utilizes phase-coded waveforms. Usually these are bi-phase modulated waveforms; they yield the widest bandwidth for a given sequence length.

Example of a bi-phase modulated waveform of length five. \( \tau_u \) is the illumination length of the pulse (uncompressed pulse length); \( \tau_s \) is the subpulse length.

Types of codes:
1. Barker sequences
2. Pseudorandom sequences
3. Frank codes
Barker Sequences

Characteristics:

- $N$ is the number of bits in the sequence
- Its matched filter output (the autocorrelation function of the sequence) contains only three absolute values: 0, 1, and $N$
- There are only seven known sequences of lengths 2, 3, 4, 5, 7, 11, and 13
- The longest sequence is only 13 bits (security problems)
- All sidelobes are the same level. Levels range from 6 dB to 22.3 dB
Pulse Compressor/Expander

\[ \tau_c \]

**Diagram:**
- **Input:** \( \tau_c \)
- **Delay Line:** \( \tau_c \) blocks
- **Weighting:** Numbers 1 and -1
- **Summer:** \( \Sigma \)
- **Output:** \( \tau_c \) blocks

**Equations:**
\[ \tau_c \]

**Legend:**
- \( \tau_c \): Compressed or expanded pulse duration
- \( \tau_u \): Uncompressed pulse duration
- \( \Sigma \): Summation point

**Diagram Details:**
- Four delay line blocks in series:
  - First two blocks have weight 1
  - Last two blocks have weight 1 and -1
- Output block shows the pulse duration variations.
The Ideal Radar Antenna

• Search: Low sidelobes
  High gain on transmit
  Fast sector coverage
  Wide bandwidth
  High power on transmit
  High signal-to-noise ratio on receive

• Tracking: Low sidelobes
  Narrow beam
  Accurate beam pointing
  Wide bandwidth
  High signal-to-noise ratio on receive

• In general: Physical limitations (size, weight, volume, etc.)
  Low cost
  Maintainability
  Robust with regard to failures; built in test (BIT)
  Ability to upgrade
  Resistant to countermeasures
Classification of antennas by size (relative to wavelength).

Let $\ell$ be the antenna dimension:

1. **electrically small**, $\ell << \lambda$: primarily used at low frequencies where the wavelength is long

2. **resonant antennas**, $\ell \approx \lambda / 2$: most efficient; examples are slots, dipoles, patches

3. **electrically large**, $\ell >> \lambda$: can be composed of many individual resonant antennas; good for radar applications (high gain, narrow beam, low sidelobes)

Classification of antennas by type:

1. reflectors
2. lenses
3. arrays

Other designations: wire antennas, aperture antennas, broadband antennas
Lens Antenna
Solid Angles and Steradians

Plane angles: \( s = R \theta \), if \( s = R \) then \( \theta = 1 \) radian

Solid angles: \( \Omega = A / R^2 \), if \( A = R^2 \), then \( \Omega = 1 \) steradian
Antenna Far Field

Far field conditions:
In the antenna far field:

\[ R > \frac{2D^2}{\lambda}, \quad D \gg \lambda, \text{ and } R \gg \lambda \]

1. \( E_R = 0 \)
2. \( E_\theta, E_\phi \propto \frac{1}{R} \)
3. wavefronts are spherical
Antenna Pattern Features

\[ \text{GAIN (dB)} \]

\[ \theta \]

\[ \theta_s \]

\[ \text{SCAN ANGLE} \]

\[ \text{PEAK GAIN} \]

\[ \text{MAXIMUM SIDELOBE LEVEL} \]
Antenna Refresher (2)

Directive gain is a measure of the antenna’s ability to focus energy

\[ G_D(\theta, \phi) = \frac{\text{radiation intensity in the direction } (\theta, \phi)}{\text{radiated power/}4\pi} \]

Radiation intensity in the direction \((\theta, \phi)\) in units of W/sr (sr = steradian):

\[ U(\theta, \phi) = R^2 |\tilde{W}(\theta, \phi)| = \frac{R^2}{Z_o} \tilde{E}(\theta, \phi) \cdot \tilde{E}(\theta, \phi)^* = \frac{R^2}{Z_o} |\tilde{E}(\theta, \phi)|^2 \]

Maximum radiation intensity is \(U_{\text{max}} = U(\theta_{\text{max}}, \phi_{\text{max}}) = \frac{R^2}{Z_o} |\tilde{E}_{\text{max}}|^2\)

Average radiation intensity:

\[ U_{\text{ave}} = \frac{1}{4\pi} \int_0^{2\pi} \int_0^{\pi} U(\theta, \phi) \sin \theta d\theta d\phi = \frac{1}{4\pi Z_o} \int_0^{2\pi} \int_0^{\pi} |\tilde{E}(\theta, \phi)|^2 R^2 \sin \theta d\theta d\phi \]

In the far-field of an antenna \(E_R = 0\) and \(E_\theta, E_\phi \propto 1/R\). The beam solid angle is

\[ \Omega_A = \frac{1}{|\tilde{E}_{\text{max}}|^2} \int_0^{2\pi} \int_0^{\pi} |\tilde{E}(\theta, \phi)|^2 \sin \theta d\theta d\phi = \frac{1}{|\tilde{E}_{\text{norm}}(\theta, \phi)|^2} \int_0^{2\pi} \int_0^{\pi} |\tilde{E}_{\text{norm}}(\theta, \phi)|^2 \sin \theta d\theta d\phi \]

(Skolnik uses \(B\))
Antenna Refresher (3)

The directive gain can be written as

$$G_D(\theta, \phi) = \frac{4\pi}{\Omega_A} \left| \vec{E}_{\text{norm}}(\theta, \phi) \right|^2$$

The maximum value of the directive gain occurs in the direction of the main beam peak for a focused antenna. The maximum value of the directive gain is called the directivity. Since the maximum value of $\left| \vec{E}_{\text{norm}}(\theta, \phi) \right|^2$ is one,

$$G_D = G_D(\theta, \phi)_{\text{max}} = \frac{4\pi}{\Omega_A}$$

Directive gain only depends on the antenna pattern. It does not include any losses incurred in forming the pattern.

Gain includes the effect of loss

$$G(\theta, \phi) = G_D(\theta, \phi) \rho$$

where $\rho$ is the antenna efficiency. Sources of loss depend on the particular type of antenna. Most electrically large antennas have losses due to nonuniform aperture illumination, $\rho_a$, and mismatch loss (reflection of energy at the input terminals), $\rho_m$. Therefore $\rho = \rho_a \rho_m$. 
Directivity Example

Example: An antenna has a far-field pattern of the form

\[ \vec{E}(\theta, \phi) = \begin{cases} \hat{\theta} E_0 \cos^n \theta e^{-jkR/R}, & \theta < \pi/2 \\ 0, & \theta > \pi/2 \end{cases} \]

where \( n \) is an integer. The normalized electric field is

\[ |\vec{E}_{\text{norm}}| = \left| \frac{E_0 \cos^n \theta e^{-jkR/R}}{E_0 e^{-jkR/R}} \right| = \cos^n \theta, \quad \theta < \pi/2 \]

The resulting beam solid angle is

\[ \Omega_A = \frac{\pi}{2 \pi} \int_0^{\pi/2} \int_0^{\pi/2} \cos^n \theta^2 \sin \theta d\theta d\phi = 2\pi \left[ \frac{\cos^{2n+1} \theta}{2n+1} \right]_0^{\pi/2} = \frac{2\pi}{2n+1} \]

and directivity

\[ G_D = \frac{4\pi}{\Omega_A} = \frac{4\pi}{\frac{2\pi}{(2n+1)}} = 2(2n+1) \]
The polarization loss factor (PLF)† between the antenna and incident field is

\[
\text{PLF}, \rho = \left| \frac{|\bar{E}_{\text{inc}} \cdot \hat{h}_e|^2}{|\bar{E}_{\text{inc}}|^2 |\hat{h}_e|^2} \right| = \left| \frac{\bar{E}_{\text{inc}} \cdot \hat{h}_e}{|\bar{E}_{\text{inc}}| |\hat{h}_e|} \right|^2
\]

A summary of polarization losses for polarization mismatched antennas is depicted in the figure.

† Also called polarization efficiency or polarization mismatch factor. Sometimes \( \hat{h}_e \) is conjugated since PLF is generally defined for the antenna transmitting.
Reflector Antennas

A singly curved reflector is generated by translating a plane curve (such as a parabola) along an axis. The radius of curvature in one dimension is finite; in the second dimension it is infinite. The focus is a line, and therefore a linear feed antenna is used.

A doubly curved reflector has two finite radii of curvature. The focus is a point. Spherical wave sources are used as feeds.
Parabolic Reflector Antenna

Spherical waves emanating from the focal point are converted to plane waves upon reflection from the parabolic surface. The ratio \( f / D \) is a design parameter. Some important relationships:

\[
\begin{align*}
  r &= \frac{2f}{1 + \cos \psi} \\
  \psi_e &= 2 \tan^{-1}\left(\frac{1}{4f/D}\right)
\end{align*}
\]
Parabolic Reflector Antenna Losses

1. **Feed blockage** reduces gain and increases sidelobe levels

   ![Feed Blockage Diagram]

2. **Spillover** reduces gain

   ![Spillover Diagram]
Other Reflector Configurations
Reflector Example (1)

Example: A circular parabolic reflector with $f/D = 0.5$ has a feed with a pattern $E(\psi) = \cos \psi$ for $\psi \leq \pi/2$. The aperture illumination is

$$A(\psi) = \frac{e^{-jkr}}{r} |E(\psi)| = \frac{e^{-jkr}}{r} \cos \psi$$

$$|A(\psi)| = \cos \psi (1 + \cos \psi) / (2f)$$

$$\psi_e = 2 \tan^{-1} \left( \frac{1}{4f/D} \right) = (2)(26.56) = 53.1^\circ$$

The edge taper is

$$\frac{|A(\psi_e)|}{|A(0)|} = \frac{\cos \psi_e (1 + \cos \psi_e) / (2f)}{2/(2f)} = 0.4805 = -6.37 \text{ dB}$$

The feed pattern required for uniform illumination is

$$\frac{|A(\psi_e)|}{|A(0)|} = \frac{|E(\psi)| (1 + \cos \psi) / 2f}{|E(0)| / f} = \frac{|E(\psi)| (1 + \cos \psi)}{2} \equiv 1 \Rightarrow |E(\psi)| = \frac{2}{1 + \cos \psi} = \sec^2 \left( \frac{\psi}{2} \right)$$
Reflector Example (2)

The spillover loss is obtained from fraction of feed radiated power that falls outside of the reflector edge angles. The power intercepted by the reflector is

\[
P_{\text{int}} = \int_{0}^{2\pi} \int_{0}^{\psi_e} \cos^2 \psi \sin \psi \, d\phi \, d\psi = 2\pi \int_{0}^{\psi_e} \cos^2 \psi \sin \psi \, d\psi
\]

\[
= -2\pi \left[ \frac{\cos^3 \psi}{3} \right]_{0}^{\psi_e} = 0.522\pi
\]

The total power radiated by the feed is

\[
P_{\text{rad}} = \int_{0}^{2\pi} \int_{0}^{\pi/2} \cos^2 \psi \sin \psi \, d\phi \, d\psi = 2\pi \int_{0}^{\pi/2} \cos^2 \psi \sin \psi \, d\psi
\]

\[
= -2\pi \left[ \frac{\cos^3 \psi}{3} \right]_{0}^{\pi/2} = 0.667\pi
\]

Thus the fraction of power collected by the reflector is

\[
P_{\text{int}} / P_{\text{rad}} = 0.522 / 0.667 = 0.78
\]

This is the spillover efficiency, which in dB is \(10 \log(0.78) = -1.08 \text{ dB}\).
Radiation by a Line Source (1)

Differential radiated field at the observation point from a differential length of source located at $x'$ (unit current amplitude):

$$dE_x = \frac{jkZ_o e^{-jk(R-x'sin\theta)}}{4\pi |R-x'sin\theta|} dx' \approx \frac{jkZ_oe^{-jkR}}{4\pi R} e^{jkx'sin\theta} dx'$$
Radiation by a Line Source (2)

Assume that the amplitude and phase along the source vary as \( A(x') \) and \( \Psi(x') \). The total radiated field from the line source is:

\[
E_x = \int dE_x = \frac{jkZ_o e^{-jkR}}{4\pi R} \int_{-D/2}^{D/2} A(x') e^{jk\Psi(x')} e^{jkx'\sin\theta} \, dx'
\]

Note that this is in the form of a Fourier transform between the domains \( x' \) and \( k \sin \theta \).

**Example:** \( A(x') = 1 \) and \( \Psi(x') = 0 \) (uniform illumination)

\[
E_x = \int dE_x = \frac{jkZ_o e^{-jkR}}{4\pi R} \int_{-D/2}^{D/2} e^{jkx'\sin\theta} \, dx' = D \text{sinc}\left(\frac{kD}{2} \sin \theta\right)
\]

In the far-field only the \( \theta \) and \( \phi \) components exist

\[
E_{\theta} = E_x \cos \theta = \frac{jk D Z_o e^{-jkR}}{4\pi R} \cos \theta \text{sinc}\left(\frac{kD}{2} \sin \theta\right)
\]

Note that \( E_{\phi} = E_x \sin \phi = 0 \) since \( \phi = 0 \). A uniform aperture function is a “spatial pulse” and its Fourier transform is a \( \text{sinc} \) function in the spatial frequency domain \( (k \sin \theta) \).
Arrays are collections of antennas that are geometrically arranged and excited to achieve a desired radiation pattern. Example: a linear array of dipoles

Assume:  
1. equally spaced elements  
2. uniformly excited (equal power to all elements)  
3. identical elements  
4. neglect “edge effects” (mutual coupling changes near edges)

In the far field vectors from the elements to the observation point are approximately parallel so that $R_n = R_1 - (n-1)d \sin \theta$
Array Antennas (2)

The element pattern for the array is the radiation pattern \( E_\theta \) of a short dipole of length \( \Delta \ (\Delta \ll \lambda) \)

\[
g_n(\theta) = \frac{jI_o\Delta}{4\pi} \frac{e^{-jkR_n}}{R_n} Z_o k \cos \theta = \frac{jI_o\Delta}{4\pi} \frac{e^{-j(kR_1-(n-1)\psi)}}{R_1} Z_o k \cos \theta = g_1(\theta)e^{j(n-1)\psi}
\]

where \( \psi = kd \sin \theta \). Since \( R_n \gg nd \sin \theta \) we have replaced \( R_n \) in the denominator with \( R_1 \) which is approximately \( R_n \). The total far field of the array is given by

\[
E(\theta) = \sum_{n=1}^{N} g_n(\theta) = g_1(\theta) \sum_{n=1}^{N} e^{jkd(n-1)\sin \theta} = g_1(\theta) \sum_{n=0}^{N-1} \left( e^{j\psi} \right)^n
\]

\[
= g_1(\theta) \frac{1 - e^{jN\psi}}{1 - e^{j\psi}} = g_1(\theta) \frac{\sin(N\psi/2)}{\sin(\psi/2)} e^{j(N-1)\psi/2}
\]

The magnitude gives the radiation pattern magnitude

\[
|E(\theta)| = |g_1(\theta)| \frac{\sin(N\psi/2)}{\sin(\psi/2)} = |\text{ELEMENT FACTOR (EF)}| \cdot |\text{ARRAY FACTOR (AF)}|
\]

This result holds in general for an array of identical elements and is referred to as the principle of pattern multiplication. The array factor is only a function of the array geometry and excitation; the element factor only depends on the element characteristics.
Visible Region

The region of the array factor that corresponds to $-90^\circ \leq \theta \leq 90^\circ$ is referred to as the visible region.
Array Antennas (3)

Grating lobes occur when the denominator of the array factor is zero, or

\[ \psi_m / 2 = \pi n \Rightarrow \sin \theta_m = m\lambda / d \Rightarrow \theta_m = \sin^{-1}(m\lambda / d) \]

for \( m = \pm 1, \pm 2, \ldots \)
Recall that there is a Fourier transform relationship between a continuous aperture distribution $A(x')$ and the radiation pattern $E(k \sin \theta)$. An array can be viewed as a sampled version of a continuous aperture, and therefore the array excitation function and far-field pattern are related by the discrete Fourier transform. The discrete Fourier transform is usually implemented using the fast Fourier transform (FFT) algorithm. Note the similarity between the FFT and Butler matrix. Grating lobes are a form of aliasing, which occurs because the Nyquist sampling theorem has been violated.

Cooley-Tukey FFT (1965)       Butler matrix feed (1960)
Array Factor for 2D Arrays

Previous results for one dimension can be extended to two dimensions. Let the array lie in the $x - y$ plane with element spacings $d_x$ and $d_y$. The number of elements are $N_x$ and $N_y$. For large arrays with no grating lobes the gain can be expressed as

$$G(\theta, \phi) = \frac{4\pi A_p \rho}{\lambda^2} \left[ \frac{g_1(\theta, \phi)}{g_{1\text{max}}} \right]^2 \left[ \frac{\sin(N_x(\psi_x - \psi_{sx})/2)}{N_x \sin((\psi_x - \psi_{sx})/2)} \right]^2 \left[ \frac{\sin(N_y(\psi_y - \psi_{sy})/2)}{N_y \sin((\psi_y - \psi_{sy})/2)} \right]^2$$

where

$$\psi_x = kd_x \sin \theta \cos \phi, \quad \psi_{sx} = kd_x \sin \theta_s \cos \phi_s$$
$$\psi_y = kd_y \sin \theta \sin \phi, \quad \psi_{sy} = kd_y \sin \theta_s \sin \phi_s$$

The physical area of the array is approximately $A_p = d_x d_y N_x N_y$. The main beam direction is given by $(\theta_s, \phi_s)$. 
Gain of Phased Arrays

From the definition of directive gain:

\[ G_D = \frac{4\pi}{\Omega_A} |\bar{E}_{\text{norm}}|^2 \]

This cannot be reduced to a closed form expression in general. However, assuming that the principle of pattern multiplication holds and that the array is large

\[
G_D = \frac{4\pi A_e}{\lambda^2} |A F_{\text{norm}}(\theta, \phi)|^2 |g_{\text{norm}}(\theta, \phi)|^2
\]

where the subscript “norm” denotes normalized (i.e., divided by the maximum value). As usual, \( A_e = \rho A_p \) (efficiency times physical aperture area)

\[ A_p \approx D_x D_y \]
Array Elements and Ground Planes

Ground planes are used to increase directivity. If the ground plane is a perfect conductor and infinite, the method of images can be used. For a horizontal dipole:

\[
g(\theta) + g(\theta) = \frac{2h}{\cos(\theta)}
\]

For a vertical dipole:

\[
g(\theta) + g(\theta) = \frac{2h}{\cos(\theta)}
\]
Array of Dipoles Above a Ground Plane
Series Fed Waveguide Slot Arrays
Low Probability of Intercept Radar (LPIR)

Low probability of intercept (LPI) strategy employs:

1. Wideband “noise-like” waveforms
2. Limit radiated power to the absolute minimum required for tracking or detection (power management). Low $P_t$ also reduces clutter illumination. Sensitivity time control (STC) can be used in conjunction with power management to reduce clutter return by reducing the receiver gain for near-in targets. Reducing $G$ as a function of $R$ is equivalent to reducing $G$ as a function of $t$.
3. Control spatial radiation characteristics:
   - narrow beams
   - rapid scanning (short target dwells)
   - low sidelobe levels (definitions shown in table are not standardized)
     - anti-jam
     - reduced clutter illumination

<table>

Antenna Pattern Control

Common aperture distribution functions:

1. **Chebyshev**: yields the minimum beamwidth for a specified sidelobe level; all sidelobes are equal; only practical for a small number of elements.
2. **Binomial**: has no sidelobes; only practical for a small number of elements.
3. **Taylor**: specify the maximum sidelobe level and rate of falloff of sidelobe level.
4. **Cosine-on-a-pedestal**: (cosine raised to a power plus a constant) wide range of sidelobe levels and falloff rates; Hamming window is one of these.
5. **Bayliss**: for low sidelobe difference beams.

Practical limitations: Manufacturing and assembly errors

Pattern synthesis: given a specified pattern, find the required aperture distribution

1. **Fourier-integral method**: take the inverse Fourier transform of the far-field pattern to obtain the aperture distribution.
2. **Woodward’s method**: use the sinc(·) as a sampling function and find the required weights to match the desired pattern.

For a focused beam the amplitude distribution is always symmetric about the center of the array. To scan a focused beam a **linear phase** is introduced across the antenna aperture.
Tapered Aperture Distributions

The shape of the aperture distribution can be used to reduce the sidelobes of the pattern.

Performance can be computed from Table 9.1 in Skolnik

| Type of distribution, $|z| < 1$ | Relative gain | Half-power beamwidth, deg | Intensity of first sidelobe, dB below maximum intensity |
|-----------------------------------|----------------|---------------------------|--------------------------------------------------------|
| Uniform; $A(z) = 1$               | 1              | $51\lambda/a$             | 13.2                                                   |
| Cosine; $A(z) = \cos^n(\pi z/2)$:|                |                           |                                                       |
| $n = 0$                           | 1              | $51\lambda/a$             | 13.2                                                   |
| $n = 1$                           | 0.810          | 69$\lambda/a$             | 23                                                    |
| $n = 2$                           | 0.667          | 83$\lambda/a$             | 32                                                    |
| $n = 3$                           | 0.575          | 95$\lambda/a$             | 40                                                    |
| $n = 4$                           | 0.515          | 111$\lambda/a$            | 48                                                    |
| Parabolic; $A(z) = 1 - (1 - \Delta)z^2$: |                |                           |                                                       |
| $\Delta = 1.0$                    | 1              | $51\lambda/a$             | 13.2                                                   |
| $\Delta = 0.8$                    | 0.994          | $53\lambda/a$             | 15.8                                                   |
| $\Delta = 0.5$                    | 0.970          | $56\lambda/a$             | 17.1                                                   |
| $\Delta = 0$                      | 0.833          | $66\lambda/a$             | 20.6                                                   |
| Triangular; $A(z) = 1 - |z|$     | 0.75           | $73\lambda/a$             | 26.4                                                   |
| Circular; $A(z) = \sqrt{1 - z^2}$ | 0.865          | $58.5\lambda/a$           | 17.6                                                   |
| Cosine-squared plus pedestal;     |                |                           |                                                       |
| $0.33 + 0.66 \cos^2(\pi z/2)$    | 0.88           | $63\lambda/a$             | 25.7                                                   |
| $0.08 + 0.92 \cos^2(\pi z/2)$, Hamming | 0.74          | $76.5\lambda/a$           | 42.8                                                   |
Example of Pattern Synthesis

Example: What pattern function provides uniform ground illumination?

\[ P_r \propto \frac{G^2}{R^4} \]

\[ R_o = R \cos \theta \]

From the RRE,

\[ \frac{G(0)^2}{R_o^4} = \frac{G(\theta)^2}{R^4} \]

or

\[ G(\theta) = G(0) \frac{R^2}{R_o^2} = G(0) \csc^2 \gamma \]

Shown below is a typical synthesized pattern using Woodward’s method.
Calculation of Aperture Efficiency

Continuous aperture

\[ \rho_a = \frac{\left| \int_{-L_x/2}^{L_x/2} \int_{-L_y/2}^{L_y/2} A(x,y)\,dx\,dy \right|^2}{\int_{-L_x/2}^{L_x/2} \int_{-L_y/2}^{L_y/2} A_p(x,y)\,dx\,dy} \]

Discrete Array

\[ \rho_a = \frac{\sum_{n=1}^{N_x} \sum_{m=1}^{N_y} |A_{mn}|^2}{N_x N_y \sum_{n=1}^{N_x} \sum_{m=1}^{N_y} |A_{mn}|^2} \]

Example: Cosine distribution: \( A(x) = \cos\left\{ \frac{\pi x}{L_x} \right\}, \quad -L_x / 2 \leq x \leq L_x / 2 \)

\[ \rho_a = \frac{\left\{ \int_{-L_x/2}^{L_x/2} \cos\left\{ \frac{\pi x}{L_x} \right\} dx \right\}^2}{\int_{-L_x/2}^{L_x/2} \cos^2\left\{ \frac{\pi x}{L_x} \right\} dx} = \frac{4(L_x / \pi)^2}{2L_x(L_x / 4)} = \frac{8}{\pi^2} \approx -0.91 \text{ dB} \]
**Efficiency Example**

**Example:** Require a fan beam generated by a cylindrical paraboloid with a line source feed that provides uniform illumination in azimuth and \( \cos(\pi y' / D_y) \) in elevation.

**Figure:**
- **PARABOLIC REFLECTOR**
- **LINE SOURCE**

Sidelobe levels from Table 9.1:
- uniform distribution in azimuth (x):
  - SLL = 13.2 dB
- cosine in elevation (y):
  - SLL = 23 dB

Find \( D_x \) and \( D_y \) for azimuth and elevation beamwidths of 2 and 12 degrees:

\[
\theta_{el} = \frac{69 \lambda}{D_y} = 12^\circ \quad \Rightarrow \quad D_y = 5.75 \lambda
\]
\[
\theta_{az} = \frac{51 \lambda}{D_x} = 2^\circ \quad \Rightarrow \quad D_x = 25.5 \lambda
\]

The aperture efficiency is \( \rho_a = (1)(0.81) \) and the gain is:

\[
G = \frac{4 \pi A_p}{\lambda^2} \quad \rho = \frac{4 \pi (5.75 \lambda)(25.5 \lambda)}{\lambda^2} \quad (1)(0.81) = 1491.7 = 31.7 \text{ dB}
\]
Array Example (1)

Example: Design an array to meet the following specifications:

1. Azimuth sidelobe level 30 dB
2. ±45 degree scan in azimuth; no elevation scan; no grating lobes
3. Elevation HPBW of 5 degrees
4. Gain of at least 30 dB over the scan range

Restrictions:
1. Elements are vertical ($\hat{y}$) dipoles over a ground plane
2. Feed network estimated to have 3 dB of loss
3. Dipole spacings are: $0.4\lambda \leq d_x \leq 0.8\lambda$ and $0.45\lambda \leq d_y \leq 0.6\lambda$
Array Example (2)

Restrictions (continued):

4. errors and imperfections will increase the SLL about 2 dB so start with a $-32$ dB sidelobe distribution ($\rho_a = 0.81$): $A(x') = 0.2 + 0.8 \cos^2(\pi x' / 2)$

5. minimize the number of phase shifters used in the design

**Step 1**: start with the gain to find the required physical area of the aperture

$$G = G_D \rho = \frac{4 \pi A_p}{\lambda^2} \rho \cos \theta \geq 30 \text{ dB}$$

$\cos \theta$ is the projected area factor, which is a minimum at 45 degrees. The efficiency includes tapering efficiency (0.81) and feed loss (0.5). Therefore

$$G = \frac{4 \pi A_p}{\lambda^2} (0.707)(0.81)(0.5) = 10^3$$

or, $A_p / \lambda^2 = (D_x / \lambda)(D_y / \lambda) \approx (N_x d_x / \lambda)(N_y d_y / \lambda) = 278.1$.

**Step 2**: uniform illumination in elevation; must have a HPBW of 5 degrees

$$\left| \frac{\sin \left( N_y k d_y \sin \theta / 2 \right)}{N_y \sin \left( k d_y \sin \theta / 2 \right)} \right|_{\theta = 2.5^\circ} = 0.707 \quad \Rightarrow \quad D_y = N_y d_y = 10 \lambda$$
Array Example (3)

This leads to $D_x = A_p / D_y = 28\lambda$. To minimize the number of elements choose the largest allowable spacing: $d_y = 0.6\lambda \Rightarrow N_y = D_y / d_y = 17$

Step 3: azimuth spacing must avoid grating lobes which occur when

$$\sin \theta_n - \sin \theta_s = n\lambda / d_x \quad (\theta_n \leq -90^\circ, n = -1, \theta_s = 45^\circ)$$

$$-1 - 0.707 = -\lambda / d_x \Rightarrow d_x \leq 0.585\lambda$$

Again, to minimize the number of elements, use the maximum allowable spacing ($0.585\lambda$) which gives $N_x = D_x / d_x = 48$. Because the beam only scans in azimuth, one phase shifter per column is sufficient.
Array Example (4)

Step 4: Find the azimuth beamwidth at scan angles of 0 and 45 degrees.

Letting $\theta_H = \theta_B / 2$, the array factor at the half power points is

$$\left| \sum_{n=1}^{N} \left[ 0.2 + 0.8 \cos^2 \left( \frac{\pi x_n}{2} \right) \right] \exp \left[ j k x_n (\pm \sin \theta_H - \sin \theta_s) \right] \right| = 0.707$$

where

$$x_n = \frac{2n - (N + 1)}{2} d \quad (N = 48, d = 0.585\lambda)$$

Solve this numerically for $\theta_s = 0$ and 45 degrees. Note that the beam is not symmetrical when it is scanned to 45 degrees. Therefore the half power angles are different on the left and right sides of the maximum.

$\theta_s = 0^\circ: \quad \theta_{H^+} = -\theta_{H^-} = 1.2^\circ \Rightarrow \text{HPBW, } \theta_B = \theta_{H^+} - \theta_{H^-} = 2(1.2) = 2.4^\circ$

$\theta_s = 45^\circ: \quad \theta_{H^+} = 46.72^\circ, \quad \theta_{H^-} = 43.33^\circ \Rightarrow \text{HPBW, } \theta_B = 46.72^\circ - 43.33^\circ = 3.39^\circ$

We have not included the element factor, which will affect the HPBW at 45 degrees.
Calculation of Antenna Temperature

The antenna collects noise power from background sources. The noise level can be characterized by the antenna temperature

\[
T_A = \frac{\int_0^\pi \int_0^{2\pi} T_B(\theta, \phi) G(\theta, \phi) \sin \theta \, d\theta \, d\phi}{\int_0^\pi \int_0^{2\pi} G(\theta, \phi) \sin \theta \, d\theta \, d\phi}
\]

\(T_B\) is the background brightness temperature and \(G\) the antenna gain.
# Multiple Beam Antennas (1)

Several beams share a common aperture (i.e., use the same radiating elements)

<table>
<thead>
<tr>
<th>Arrays</th>
<th>Reflectors</th>
<th>Lenses</th>
</tr>
</thead>
<tbody>
<tr>
<td><img src="image1" alt="Array Diagram" /></td>
<td><img src="image2" alt="Reflectors Diagram" /></td>
<td><img src="image3" alt="Lenses Diagram" /></td>
</tr>
</tbody>
</table>

**Advantages:**
- Cover large search volumes quickly
- Track multiple targets simultaneously
- Form “synthetic” beams

**Disadvantages:**
- Beam coupling loss
- Increased complexity in the feed network

Sources of beam coupling loss: (1) leakage and coupling of signals in the feed network, and (2) non-orthogonality of the beam patterns
Multiple Beam Antennas (2)

Multiple beams are a means of increasing the rate of searching radar resolution cells (i.e., the radar system bandwidth). The overall system bandwidth depends on the number of range cells ($N_{\text{range}}$), Doppler cells ($N_{\text{dop}}$), and angle cells ($N_{\text{ang}}$):

$$N_{\text{sys}} = N_{\text{range}} \times N_{\text{dop}} \times N_{\text{ang}}$$

$$N_{\text{sys}} = \left( \frac{1}{f_p \tau} \right) \times (f_p t_{\text{tot}}) \times \left( \frac{\Omega_s}{\theta_e \theta_a} \right) = \frac{t_f}{\tau} \frac{t_f}{t_{\text{tot}}}$$

The bandwidth of the system can be increased by adding more beams and receivers. If the instantaneous bandwidth of a receiver is $B \approx 1/\tau$ and $m$ channels are used then

$$N_{\text{sys}} = t_f B_{\text{eff}} \quad \Rightarrow \quad B_{\text{eff}} = mB$$

Example: A radar with 8 beams, a pulse width of 0.25 $\mu$s, and a rotation rate of 10 rpm ($t_f = 6$ sec) has $N_{\text{sys}} = \frac{(6)(8)}{0.25 \times 10^{-6}} = 2 \times 10^8$ resolution cells and an effective system bandwidth of 32 MHz.
Radiation Patterns of a Multiple Beam Array

\[ N = 30 \]
\[ d = 0.4\lambda \]
\[ \Delta \theta_s = 2.3^\circ \]
Example of Beam Coupling Loss

For \( m \) and \( n \) to be orthogonal beams:

\[
\frac{1}{Z_o} \int_0^{\pi} \int_0^{\pi} \mathbf{E}_m(\theta, \phi) \cdot \mathbf{E}_n^*(\theta, \phi) R^2 \sin \theta d\theta d\phi = 0
\]

**Example:** If the beams are from a uniformly illuminated line source then \( \mathbf{E}_n(\theta, \phi) \), \( \mathbf{E}_m(\theta, \phi) \propto \text{sinc}(\cdot) \) and adjacent beams are orthogonal if the crossover level is 4 dB.
Active Versus Passive Array

Active = amplification before beamforming; Passive = amplification after beamforming

CONVENTIONAL (LNA PER BEAM)

ACTIVE (LNA PER RADIATING ELEMENT)
Active Versus Passive Antenna Example

Example: Consider the receiver channel shown. Find the noise figure for the circuit and also when the locations of the cable and amplifier are switched. In the latter case, what is the improvement when a low noise amplifier with NF of 1.5 dB is used? (In general, a LNA has a NF near 1.)

The effective noise figure of the dashed box is

$$F_e = F_1 + \frac{F_2 - 1}{A_1} = L_x + \frac{\text{NF} - 1}{1/L_x} = 10 + \frac{4 - 1}{0.1} = 40 \rightarrow 16 \text{ dB}$$

If we use the LNA

$$F_e = 10 + \frac{1.4 - 1}{0.1} = 14 \rightarrow 11.5 \text{ dB}$$

However, if we use a LNA before the cable

$$F_e = 1.4 + \frac{10 - 1}{100} = 1.49 \rightarrow 1.73 \text{ dB}$$
Comparison of SNR: Active vs. Passive

PASSIVE
1. Amplification after beamforming
2. The antenna gain is the SNR improvement (neglecting noise introduced by the antenna).

ACTIVE
1. Amplification before beamforming
2. The SNR performance can be significantly better than the gain indicates.
3. Losses “behind” the amplifier can be recovered, including beam coupling losses.
4. SNR degradation is only determined by the aperture efficiency.
5. Since amplifiers are non-reciprocal devices (transmit in one direction) separate channels must be provided for transmission and reception.

- In general, use a LNA and place it as close to the antenna element as possible.
- Photo shows a transmit-receive (T/R) module for an active airborne phased array
Digital Phase Shifters

Phase shifters are used to “tilt” the phase across the array aperture for scanning. Diode phase shifters are only capable of providing discrete phase intervals. A \( n \) bit phase shifter has \( 2^n \) phase states. The quantization levels are separated by \( \Delta \phi = \frac{360^\circ}{2^n} \). The fact that the exact phase cannot always be obtained results in:

1. gain loss
2. increase in sidelobe level
3. beam pointing error

Example: truncation or “rounding down”
Effect of Phase Shifter Roundoff Errors

Truncation causes beam pointing errors. Random roundoff methods destroy the periodicity of the quantization errors. The resultant rms error is smaller than the maximum error using truncation.

Linear array, 60 elements, \( d = 0.4\lambda \)
4 bit phase shifters
True Time Delay (TTD) Scanning

Array factor for an array with the beam scanned to angle $\theta_s$:

$$AF(\theta) = \sum_{n=1}^{N} A_n e^{j(n-1)kd(\sin\theta - \sin\theta_s)} = \sum_{n=1}^{N} A_n e^{j(n-1)(\psi - \psi_s)}$$

where $\psi_s = kd \sin\theta_s$. For a uniformly excited array ($A_n = 1$)

$$|AF(\theta)| = \left| \frac{\sin\left(\frac{Nkd}{2}(\sin\theta - \sin\theta_s)\right)}{\sin\left(\frac{kd}{2}(\sin\theta - \sin\theta_s)\right)} \right| = \frac{\sin\left(N(\psi - \psi_s)/2\right)}{\sin\left((\psi - \psi_s)/2\right)}$$

\[\begin{align*}
\psi|_{\theta=\theta_s} - \psi_s &= 0 \\
\frac{2\pi d}{\lambda} \sin\theta_s - \psi_s &= 0 \\
\psi_s &= \frac{2\pi d}{\lambda} \sin\theta_s \\
\ell &= d \sin\theta_s
\end{align*}\]
Time Delay vs. Fixed Phase Scanning

Beam scanning using cables to provide "true time delay".

Beam scanning with phase shifters gives a phase that is constant with frequency.
Phase shifters provide a phase that is approximately constant with frequency.
Example of TTD vs. Phase Shifters

Patterns of a linear array with constant phase shift for all frequencies (left) versus true time delay phase shifters (right). \( \theta_s = 10^\circ, f_o = 1.7 \text{ GHz} \)
Time Delay Networks

Δ IS A TIME DELAY BIT

Δ IS A TIME DELAY BIT

SWITCH

TIME DELAY FIBERS
Time Delay Using Fiber Optics

Large phase shifts (electrical lengths) can be obtained with fibers. In general, the incorporation of optical devices into the antenna is referred to as photonics.
Digital Beamforming (1)

A generic digital array is shown:

- Waveforms are generated and amplified at the element level.
- Received signals are down-converted and sampled at the element.
- Baseband or IF data is sent to the beamformer (computer) for processing.

Element responses become array storage locations in the computer. The weights are added and the sums computed to find the array response. In principle, any desired beam characteristic can be achieved, including multiple beams. For coherent operation all elements must be synchronized to a common time and phase reference.
Digital Beamforming (2)

Consider an $N$ element linear array with spacing $d$ along the $z$ axis. The array factor is

$$AF(\theta, \phi) = \sum_{n=1}^{N} w_n \exp[jkd_n \cos \theta] = \sum_{n=1}^{N} A_n e^{j\alpha_n} \exp[jkd_n \cos \theta]$$

where $w_n$ is a complex weight added by the processor and $d_n = [2n - (N+1)]d/2$.

$\alpha_n = -kd_n \cos \theta_s$ to scan the main beam to $\theta_s$

$r_n(t)$ is the echo signal out of element $n$

The demodulators provide spatial samples of the exponential factor in $AF$:

$I_n = \cos[jkd_n \cos \theta]$

$Q_n = \sin[jkd_n \cos \theta]$. 

---

89
Digital Beamforming (3)

A set of 41 digital beams (only the main lobe region of each beam is plotted)

Response at the peak of each beam to two simultaneous signals (one incident from 0 degrees and the other from 42 degrees)
Monopulse Difference Beams

Example of a low sidelobe difference beam obtained using a Bayliss amplitude distribution

Formation of difference beams by subtraction of two subarrays
Sum and Difference Beamforming
Waveguide Monopulse Beamforming Network
Antenna Radomes

The purpose of a radome (from radar dome) is to protect the antenna from the harsh operational environment (aerodynamic and thermal stresses, weather, etc.). At the same time it must be electromagnetically transparent at the operating frequency of the radar. The antenna pattern with a radome will always be different than that without a radome. Undesirable effects include:

1. **gain loss** due to lossy radome material and multiple reflections
2. **beam pointing error** from refraction by the radome wall
3. **increased sidelobe level** from multiple reflections

These effects range from small for flat non-scanning antennas with flat radomes to severe for scanning antennas behind doubly curved radomes.
Radome Example: Space Shuttle Tile
Conformal Antennas & “Smart Skins”

Conformal antenna apertures conform to the shape of the platform.
1. Typically applied to composite surfaces
2. The antenna beamforming network and circuitry are interlaced with the platform structure and skin
3. They can be active antennas with processing embedded (i.e., adaptive)
4. Self-calibration and fault isolation employed (i.e., identification of failures – this is referred to as build in test equipment, BITE)
5. Can be reconfigurable (a portion of the aperture that is active can be changed)
6. Infrared (IR) and other sensors can be integrated into the antenna
Antenna Imperfections (Errors)

Causes:
1. Manufacturing and assembly tolerances
   a) machining of parts
   b) alignment and assembly
   c) material electrical properties
   d) thermal expansion and contraction
   e) gravitational deformation
2. Failures

Effects:
1. Reduced gain
2. Increased sidelobe level
3. Reduced power handling capability

Approximate degradation in gain for an array of \( N \) elements:

\[
G \approx \frac{4\pi A_e}{\lambda^2} \left( P_{\text{norm}} (1 - \Delta^2 - \delta^2) + \frac{\bar{\Delta}^2 + \bar{\delta}^2}{N \rho_a} \right)
\]

where \( P_{\text{norm}} = \frac{|\bar{E}|^2}{|\bar{E}_{\text{max}}|^2} \) = normalized error free power pattern, \( \rho_a \) = aperture efficiency, and \( \Delta^2, \delta^2 \) = variance of amplitude and phase errors, respectively (assumed to be small)
Smart Antennas (1)

Antennas with built-in multi-function capabilities are often called smart antennas. If they are conformal as well, they are known as smart skins. Functions include:

- Self calibrating: adjust for changes in the physical environment (i.e., temperature).
- Self-diagnostic (built-in test, BIT): sense when and where faults or failures have occurred.

Tests can be run continuously (time scheduled with other radar functions) or run periodically. If problems are diagnosed, actions include:

- Limit operation or shutdown the system
- Adapt to new conditions/reconfigurable

**Example:** a test signal is used to isolate faulty dipoles and transmission lines
Smart Antennas (2)

Example of a self-calibrating, self-diagnostic transmit/receive module
Transmission Line Refresher (1)

Finite length loaded transmission line:

\[ Z_o = \text{characteristic impedance; depends on line geometry and material and wavelength } \mu, \varepsilon, \lambda, \text{ and } \sigma; \text{ real for lossless lines; approximately real for low-loss lines} \]

\[ Z_L = \text{load impedance; generally complex} \]

\[ Z_{in} = \text{input impedance} \]

\[ Z_{in} = Z_o \frac{Z_L + Z_o \tanh(\gamma \ell)}{Z_o + Z_L \tanh(\gamma \ell)} \]

\[ \gamma = \alpha + j\beta = \text{propagation constant (depends on line geometry and material and frequency)} \]

For a lossless line \( \alpha = 0 \) (and low loss line \( \alpha \approx 0 \)):

\[ Z_{in} \approx Z_o \frac{Z_L + jZ_o \tan(\beta \ell)}{Z_o + jZ_L \tan(\beta \ell)} \]
Transmission Line Refresher (2)

Reflection coefficient of a load or junction:

\[ \Gamma = \frac{|E_{\text{refl}}|}{|E_{\text{inc}}|} = \frac{Z_{o2} - Z_{o1}}{Z_{o2} + Z_{o1}} \]

Voltage standing wave ratio (VSWR):

\[ s = \frac{|E_{\text{max}}|}{|E_{\text{min}}|} = \frac{1 + |\Gamma|}{1 - |\Gamma|} \quad (1 \leq s < \infty) \]

Return loss:

\[ RL = -20\log(|\Gamma|) \text{ dB} \]
Transmission Line Refresher (3)

Matching and tuning transmission line circuits:

Mismatches cause reflections, but multiple mismatches can be “tuned” by forcing the reflections to cancel (add destructively). This approach is generally narrow-band because most load impedances are a strong function of frequency.

“Off-the-shelf” hardware is usually designed to have a characteristic impedance of 50 Ω ($Z_o = 50 + j0 \Omega$). Therefore, when devices are combined, reflections will be small and the input impedance of a chain of devices independent of line lengths. For example, if $Z_L = Z_o$:

$$Z_{in} = Z_o \frac{Z_o + jZ_o \tan(\beta \ell)}{Z_o + jZ_o \tan(\beta \ell)} \rightarrow Z_o$$

Devices such as antennas and amplifiers have matching networks added to the input and output ports to provide a 50 Ω impedance.

Matching elements include: quarter-wave steps
transmission line stubs
lumped elements (resistors, capacitors and inductors)
Multiplexers

Multiplexers are frequency selective circuits used to separate signals by frequency spectrum. They are comprised of filter networks. An example is a waveguide manifold multiplexer:

\[ \Delta f_1 + \Delta f_2 + \Delta f_3 + \Delta f_4 \]

The plane at 1 appears as a short in the band \( \Delta f_1 \), but matched at other frequencies. The waveguide junction at A appears matched at \( \Delta f_1 \), but shorted at other frequencies. Similarly for planes 2, 3, 4 and junctions B, C, D. Frequency characteristic:
Rotary Joints

Microwave rotary joints allow the antenna to rotate without twisting the transmission line that feeds the antenna. Example of a coaxial rotary joint:

There is no efficient, reliable rotary joint in rectangular waveguide. Therefore, most rotary joints are made with circular waveguide because of the simple construction. Thus transitions from rectangular to circular cross sections are required.

Multichannel rotary joints are also possible for monopulse sum and difference channels.
Microwave Switches

Microwave switches are used to control signal transmission between circuit devices. A general representation of a switch is given in terms of “poles” and “throws”

Switches can be constructed in any type of transmission line or waveguide. Common types:

<table>
<thead>
<tr>
<th>Type</th>
<th>Principle</th>
<th>Applied to:</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mechanical</td>
<td>Rotating or moving parts</td>
<td>All types</td>
</tr>
<tr>
<td>Diode</td>
<td>Forward/backward bias yields low/high impedance</td>
<td>Stripline, microstrip, waveguide</td>
</tr>
<tr>
<td>Gas discharge</td>
<td>Confined gas is ionized</td>
<td>Waveguide</td>
</tr>
<tr>
<td>Circulator</td>
<td>Magnetized ferrite switches circulation direction</td>
<td>Stripline, microstrip, waveguide</td>
</tr>
</tbody>
</table>
Circulators

Circulators “circulate” the signal from port to port in the direction indicated by the arrow.

Ideally:
- Signal into port 1 emerges out port 2; signal out port 3 is zero.
- Signal into port 2 emerges out port 3; signal out port 1 is zero.
- Signal into port 3 emerges out port 1; signal out port 2 is zero.

In practice:
1. There is some insertion loss in the forward (arrow) direction. Values depend on the type of circulator. They range from 0.5 dB to several dB.
2. There is leakage in the reverse (opposite arrow) direction. Typical values of isolation are 20 to 60 dB. That is, the leakage signal is 20 to 60 dB below the signal in the forward direction.
3. Increasing the isolation comes at the expense of size and weight

Uses:
1. Allow a transmitter and receiver to share a common antenna without switching
2. Attenuate reflected signals (load the third port)
Waveguide Magic Tee

Ports 1 and 2 are the “sidearms.” Port 4 is the “sum” port and 3 the “difference” port.

<table>
<thead>
<tr>
<th>Sidearm excitation</th>
<th>Port 3</th>
<th>Port 4</th>
</tr>
</thead>
<tbody>
<tr>
<td>$A_1 = a e^{j\phi}$, $A_2 = a e^{j\phi}$</td>
<td>$A_3 = 0$</td>
<td>$A_4 = 2a$</td>
</tr>
<tr>
<td>$A_1 = a e^{j\phi}$, $A_2 = a e^{j\phi+\pi}$</td>
<td>$A_3 = 2a$</td>
<td>$A_4 = 0$</td>
</tr>
</tbody>
</table>

The term “magic” originates from the fact that it is the only 4-port device that can be simultaneously matched at all ports.
Filter Characteristics

Filters are characterized by their transfer functions $|H(f)| = |\tau| = \sqrt{1 - |\Gamma|^2}$, where $\Gamma$ is the reflection coefficient. It is usually plotted as return loss in dB ($20\log_{10}(|\Gamma|)$) or transmission loss in dB ($20\log_{10}(|\tau|)$). Note that in many cases the phase of the transfer function is also important.
Mixers (1)

Mixers are multipliers; they multiply two CW signals (sinusoids). The signal from the antenna is at the carrier frequency. The second signal generated by the local oscillator is usually lower than the carrier frequency.

\[ \propto \cos(\omega_c t) \]

\[ \propto \cos(\omega_{LO} t) \]

\[ \propto \cos(\omega_c t - \omega_{LO} t) \]

\[ \propto \cos(\omega_{LO} t) \]

The output signal contains all of the cross products obtained by multiplying the two sinusoids. By trig identity:

\[ \cos(\omega_c t) \cos(\omega_{LO} t) \propto \cos(\omega_c t - \omega_{LO} t) + \cos(\omega_c t + \omega_{LO} t) \]

The \( f_c + f_{LO} \) (i.e., \( \omega_c + \omega_{LO} \)) is discarded by filtering and receiver processing is performed on the \( f_c - f_{LO} \) term. The difference frequency \( f_c - f_{LO} \) is called the intermediate frequency (IF).
Mixers (2)

Mixers are a means of frequency conversion. Converting to a frequency lower than the carrier is done primarily for convenience. If

\[ f_{LO} < f_c \]  this process is referred to as heterodyning

\[ f_{LO} = f_c \]  this process is referred to as homodyning

We have defined a mixer as a multiplier of two sinusoids. In most cases nonlinear devices are used to perform frequency conversion. A simple example is a single-ended diode mixer:

The diode is nonlinear; that is, the output for a single frequency input not only contains an input frequency term, but all of the harmonic terms as well.
Mixers (3)

When two sinusoids are combined in a diode mixer, the harmonics of both frequencies are present as well as all of the cross products. A few of them are shown below:

These are intermodulation products and must be controlled by proper mixer design to achieve high conversion efficiency and good noise performance.

The above results are based on a "small signal analysis" which assumes that the carrier signal level is much smaller than the LO voltage.

Even if the noise at both inputs is uncorrelated, the noise at the output is partially correlated. The noise figure depends on the impedances presented to all significant harmonics, not just the carrier and LO frequencies.
**Input-Output Transfer Characteristic**

Applies to transmitters (power amplifiers) and receivers (low noise amplifiers, mixers).

The three region characteristics:
1. **linear**, \( P_{\text{out}} \propto P_{\text{in}} \)
2. **saturation**, \( P_{\text{out}} \approx \) constant
3. **nonlinear**, 

For a single input frequency \( \Rightarrow \)

\[ V_{\text{out}} \propto \frac{a_1 V_{\text{in}}}{\omega_c} + \frac{a_2 V_{\text{in}}^2}{2\omega_c} + \frac{a_3 V_{\text{in}}^3}{3\omega_c} + \cdots \]
Intermodulation Products (IP)

In the nonlinear region $V_{out} \propto a_1 V_{in} + a_2 V_{in}^2 + a_3 V_{in}^3 + \cdots$. If the input signal $V_{in}$ contains more than one frequency, say $f_1$ and $f_2$, then all combinations of the two frequencies and their harmonics will be present in the output

$$f_{pqr} = \pm p f_1 \pm q f_2 \pm r f_{LO} \quad p, q, r = 0, 1, 2, \ldots$$

These are intermodulation products (IM): $p \text{ or } q = 0$, single tone IM

$p, q, r = 1, 2, \ldots$ multi-tone IM

Example: Both stationary target return ($f_1 = f_c$) and moving target return ($f_2 = f_c + f_d$) are passed through an amplifier. The third order IM (from the $V_{in}^3$ term) can lie in the passband. IM can cause signal distortion and potentially misinterpretation as a target.
Intermodulation Example

**Example:** Mixer RF passband: \( 29 \leq f_{RF} \leq 30 \text{ GHz} \)

LO frequency: \( f_{LO} = 26 \text{ GHz} \)

IF passband: \( f_{IF} = f_{RF} - f_{LO} = \left\{ \frac{30}{29} \right\} - 26 = \left\{ \frac{3}{4} \right\} \text{ GHz} \)

Other intermodulation products: \( f_{IF} = mf_{RF} - nf_{LO} \Rightarrow f_{RF} = \frac{1}{m} \left( f_{IF} - nf_{LO} \right) \)
Amplifiers

Most receive amplifiers use gallium arsenide field effect transistors (GaAs FETs). Bipolar transistors are used at low microwave frequencies and performance is improving at higher microwave frequencies.

General circuit:

Design parameters: 1. transducer gain (ratio of the power delivered to the load to the power available from the source)  
2. stability  
3. noise figure

Typical amplifier circuit:
Low-Noise Amplifier

This is an example of older technology that uses discrete elements. Current designs use integrated circuits.

Transmitters (2)

Microwave tube classification:

**Crossed field:** The dc electric field is perpendicular to the magnetic field. The general motion of the electrons is perpendicular to both fields. These are also known as "M-type" tubes. Examples are magnetrons and crossed field amplifiers.

![Crossed field diagram]

**Linear beam:** The general direction of the electron beam is parallel or antiparallel with the field vectors. Examples are klystrons and traveling wave tubes.

![Linear beam diagram]
Klystrons

The oscillating electric field in the gap ($\vec{E}_g$) accelerates or decelerates electrons from the cathode. This causes “bunching” of the electrons into packets. They transfer their energy to the catcher cavity.
Klystron Operation

A klystron consists of a cathode and anode separated by an interaction space. In a two cavity klystron, the first cavity acts as a “buncher” and velocity modulates the electron beam. The second cavity is separated from the buncher by a drift space, which is chosen so that the AC current at the second cavity (the “catcher”) is a maximum. The second cavity is excited by the AC signal impressed on the beam in the form of a velocity modulation with a resultant production of an AC current. The AC current on the beam is such that the level of excitation of the second cavity is much greater than that in the buncher cavity, and hence amplification takes place. If desired, a portion of the amplified output can be fed back to the buncher cavity in a regenerative manner to obtain self-sustained oscillations.

The catcher cavity can be replaced by a reflector, in which case it is referred to as a reflex klystron. The reflector forces the beam to pass through the buncher cavity again, but in the opposite direction. By the proper choice of the reflector voltage the beam can be made to pass through in phase with the initial modulating field. The feedback is then positive, and the oscillations will build up in amplitude until the system losses and nonlinear effects prevent further buildup.

(From: *Foundations of Microwave Engineering*, by R. E. Collin)
Cavity Magnetron

Cross section of a typical cavity magnetron

1. anode
2. cavity
3. coupling slot
4. cathode
5. interaction space
6. coupling loop
7. strapping
Magnetron Operation

A magnetron consists of a number of identical resonators arranged in a cylindrical pattern around a cylindrical cathode. A permanent magnet is used to produce a strong magnetic field $B_o$ normal to the cross section. The anode is kept at a high voltage relative to the cathode. Electrons emitted from the cathode are accelerated toward the anode block, but the presence of the magnetic field produces a force ($-ev_rB_o$) in the azimuthal direction which causes the electron trajectory to be deflected in the same direction.

If there is present an AC electromagnetic field in the interaction space that propagates in the azimuthal direction with a phase velocity $\omega r$, strong interaction between the field and the circulating electron cloud can take place. The usual mode of operation is the $\pi$ mode where the phase change between adjacent cavities is $\pi$ radians. Each cavity with its input gap acts as a short-circuited transmission line a quarter of a wavelength long, and hence has a maximum electric field across the gap. A synchronism between the AC field and the electron cloud implies that those electrons located in the part of the field that acts to slow the electrons give up energy (and vice versa). Electrons that slow down move radially outward and are intercepted by the anode. Electrons that are accelerated by the AC field move radially inward until they are in phase with the field, and thus give up energy to the field. When the latter happens, they slow down and move to the anode. Therefore the only electrons lost from the interaction space are those that have given up a net amount of energy.

Eight Cavity Magnetron

Electron cloud in the interaction space of an eight cavity magnetron
Magnetron Basics (1)

Three fields present:

- $\vec{E}$ due to voltage applied between anode and cathode
- $\vec{B}$ due to magnet
- $\vec{E}_{RF}$ in the interaction space

If $\vec{B}$ is strong enough electrons will be prevented from reaching the anode (this is magnetic insulation). The critical value of the magnetic field density is

$$B_c = \frac{m_0 c \sqrt{\gamma^2 - 1}}{e d_e}$$

where:

- $d_e = \text{effective gap} = \frac{r_a^2 - r_c^2}{2r_a}$ ($r_a = \text{anode radius}; r_c = \text{cathode radius}$)
- $\gamma = \text{relativistic factor} = \frac{1}{\sqrt{1 - (v/c)^2}} = 1 + \frac{eV_o}{m_0 c^2}$
- $e = \text{electronic charge}; m_0 = \text{mass}; V_o = \text{beam voltage}$

The cathode orbit drift velocity is

$$\vec{v}_d = \frac{\vec{E} \times \vec{B}}{|\vec{B}|^2}$$
The Bruneman-Hartree resonance condition for mode $n$:

$$B_{BH} = \frac{2m^2}{e^2} eV_o \frac{r_a^2}{r_a^2 - r_c^2} \frac{n}{\omega_n}$$

 Usually the cavities are spaced half a wavelength at the RF. The drift velocity must equal the phase velocity. At alternating cavities the electrons reach the anode. Therefore “spokes” arise which rotate around the interaction space. RF energy grows at the expense of the kinetic and potential energy of the electrons.
Free-Electron Laser (FEL) Operation

A free electron laser consists of an electron beam, a periodic pump field and the radiation field. The electron beam passes through the pump field and begins to oscillate. (The pump field is usually a static periodic magnetic field called a “wiggler,” but in principle it can be any field capable of producing a transverse electron oscillation.) The oscillating electrons radiate, and the combination of the radiation field and wiggler field produces a beat wave which tends to bunch electrons in the axial direction. The bunching force provided by the beating of the radiation and wiggler fields is due to a so-called pondermotive wave, which is characterized by a periodic axial force. The bunched electrons radiate more coherently, thereby strengthening the radiation, which causes more bunching, then produces stronger and more coherent radiation, and so forth. The electrons in the beam are not bound to any nucleus, hence the term “free electron.”

Like all lasers, a FEL can operate as either an amplifier or oscillator. Amplifiers require high growth rates so that large gains in the radiation field can occur in a reasonable distance. This requirement generally restricts the use of FELs to millimeter wavelengths or shorter. The most important FEL attributes are broad frequency-tuning ability, high efficiency (> 40%), wide bandwidth, and high power (> 10 MW at millimeter wave frequencies).

Free-Electron Lasers

Example of a basic free electron laser

\[ \lambda = \frac{\lambda_w}{(2\gamma_o^2)(1 + K_w^2/2)} = \text{radiation wavelength} \]

\[ K_w = \frac{eB_w}{mck_w} = \text{wiggler strength parameter} \]

\[ \lambda_w = \frac{2\pi}{k_w} = \text{wiggler period; } B_w = \text{wiggler magnetic field;} \]

\[ e = \text{electron charge; } m = \text{electron rest mass; } c = \text{speed of light} \]
